Primary effects include any surface expression of the seismogenic tectonic source, including surface faulting, surface tectonic uplift, and subsidence. These effects are typically observed for shallow crustal earthquakes over a certain threshold value of magnitude, commonly considered to be between 6.0 and 6.5 Mw, being directly linked to the size, hence the energy of the earthquake. Primary effects in principle do not suffer saturation, although there is a physical limit to their dimensions (included in the XII degree). The size of primary effects is typically expressed in terms of two parameters: (i) total surface rupture length (SRL) and (ii) maximum displacement (MD). The amount of tectonic surface deformation (uplift, subsidence) is also considered in the assessment.

The focal depth and the stress environment of an earthquake obviously control the occurrence and the size of the observed effects. Two crustal earthquakes with the same energy but very different focal depths and stress environment can produce a different range of environmental effects, and, therefore, their respective local intensity values can significantly differ. Especially in volcanic areas, earthquakes of very shallow focus (c. 3–4 km) and low magnitude can be associated with the manifestation of primary effects. Taking these considerations into account, the ESI-07 scale considers the lower cutoff for the occurrence of primary effects

Intensity Scale ESI 2007 for Assessing Earthquake Intensities, Fig. 1 ESI-07 chart illustrating the main features and size parameters of the macroseismic scale for the different intensity degrees described in Appendix 1 (Modified from Reicherter et al. (2009))

(i.e., surface faulting) in intensity VII, whereas for typical crustal earthquakes (focal depth 5–15 km), in non-volcanic zones, primary effects start from intensity VIII.

Secondary Effects

Secondary effects include a wide range of phenomena affecting the natural environment, generally induced by the ground shaking. Their occurrence is typically observed in a specific range of intensities. The ESI-07 scale describes the characteristics and size of each type of secondary effect as a diagnostic feature in a range of intensity degrees. In some cases, it is only possible to establish a minimum intensity value. The total areal distribution of secondary effects grows with the size of the event, without saturation. Therefore, the ESI-07 scale uses this criterion as an independent tool for the assessment of the epicentral intensity I_0 .

EEEs are more commonly observed and characterized from intensity IV, which is the lower bound of the ESI-07 scale. Some types of environmental effects concerning hydrological anomalies may be observed even at lower degrees, but they cannot be considered as diagnostic for intensity assessments. The evaluation accuracy increases toward the highest degrees, particularly in the range where primary effects occur (typically for intensity VIII and above), preserving its resolution up to intensity XII. Indeed, effects on man and man-made structures saturate (i.e., all buildings in the epicentral area are completely destroyed) starting from intensity X of traditional scales, so that a reliable intensity becomes difficult to assess. Instead, in the same range, EEEs still provide reliable evidence for an intensity appraisal.

In the ESI-07 scale, EEEs are classified into eight main categories: (1) hydrological anomalies, (2) anomalous waves/tsunamis, (3) ground cracks, (4) slope movements, (5) tree shaking, (6) liquefaction, (7) dust clouds, and (8) jumping stones.

Hydrological anomalies (HA). Hydrological phenomena show up from intensity $\geq$ IV and saturate (i.e., their size does not increase) at intensity X. They can be divided in two groups: (a) surface

water effects including overflow, discharge variations, and increasing turbidity of rivers and lakes and (b) groundwater effects including drying up of springs, appearance of new springs, temperature changes, anomalies in chemical components, and turbidity of springs. Further useful information might be the amount and rates of variation in temperature and discharge, the presence of anomalous chemical element, the duration of the anomaly, and the time delay (the time interval between the seismic shock and the observation of the specific effect).

Anomalous waves/Tsunamis (AW). In this category are included seiches in closed basins, outpouring of water from pools and basins, and tsunami waves. In the case of tsunamis, more than the size of the tsunami wave itself, the effects on the shores (especially run-up, beach erosion, change of coastal morphology), without neglecting those on humans and man-made structures, are taken as diagnostic of the suffered intensity. These effects may already occur from intensity IV but are more diagnostic from intensities IX to XII. The definition of intensity degrees has taken advantage from previous tsunami intensity scales (e.g., Papadopoulos and Imamura 2001) and from many recent descriptions of the aforementioned effects worldwide (e.g., Lander et al. 2003).

Ground cracks (GK). Ground cracks appear from intensity IV and saturate (i.e., their size does not increase) at intensity X. Diagnostic parameters are lithology, strike and dip, maximum width, and areal density. Different dimensions of fractures are considered for soft materials (loose alluvial deposits and/or saturated soils) and hard rocks. This category also includes the occurrence of cracking, undulations, and/or pressure ridges in paved (asphalt or stone) roads.

Slope movements (SM). Slope movements, including underwater landslides, consider a wide variety of gravitational slope processes such as rockfalls, debris falls, and toppling; rock or debris slides, avalanches, and mudslides; debris-, earth-, and mudflows; and sackungen, complex landslides, and eventually lateral spreads. This category may show up at intensity IV and saturate (i.e., their size does not increase)

at intensity X. The total volume of mobilized material is diagnostic for intensity assessment. It can be roughly estimated on the basis of the landslide area when the depth of sliding mass can be reasonably estimated. The uncertainties introduced with this procedure do not appear to significantly influence the intensity evaluation. Additional useful information is maximum dimension of individual blocks (rockfalls), area affected by slope movements, density of slope movements, amount of slip, humidity, and time delay.

Liquefaction processes (LQ). Liquefactions generally materialize at intensity V or greater. The diagnostic features for liquefactions are the diameter of sand volcanoes and their lithology (silt, sands, and gravel). Saturation (i.e., their size does not increase) occurs at intensity X. Other useful characteristics are shape, the time delay, the depth of water table, and the occurrence of water and sand ejection.

Other environmental effects (OT) considered in the scale have a scarce to null preservation potential and a low diagnostic relevance, but of use of well-documented historical and recent events. Among them are the following:

- **Tree shaking (TR).** This phenomenon is reported to occur from a minimum intensity IV but noticeable for intensity VII and diagnostic from intensity VIII. It is important to record the occurrence of broken branches and the morphologic characteristics of the area (flat, slope). The definition of intensity degrees basically follows that provided by Dengler and McPherson (1993).
- **Dust clouds (DC)** are reported from intensity VIII, typically in dry areas.
- **Jumping stones (JS)** have been reported from minimum intensity IX. The size of stones and their imprint in soft soil are considered as diagnostic parameters for intensity evaluation.

Structure of the ESI-07 Scale

The ESI-07 scale (Fig. 1; Appendix 1) is structured in 12° and has been developed to be consistent with the modified Mercalli macroseismic scale (MM-31; Wood and Neumann 1931;

MM-56, Richter, 1958) and the MSK-64 (Medvedev-Sponheuer-Karnik Scale), since these are the most applied scales worldwide and include explicit references to environmental effects (especially in the highest degrees, X to XII). Comparing the ESI-07 with these other twelve-degree scales, we can identify four main intensity subsets as illustrated in Fig. 1:

From I to III: There are no environmental effects that can be used as diagnostic.

From IV to VII: Secondary environmental effects are easily observable starting from intensity IV, but only often permanent and diagnostic starting from intensity VII. Except for volcanic areas, this range of intensity degrees does not record primary effects. Within this range, effects on natural environment are less suitable for intensity assessment than effects on humans and man-made structures. Their use is therefore recommended especially in sparsely populated areas or in combination with damage-based intensity scales. Their use in field surveys for recent events will help to improve future versions of the scale. Environmental damage affects an area normally $\leq 10 \text{ km}^2$.

From VIII to X: In this range of intensities, primary and secondary environmental effects become characteristic and normally permanent and diagnostic. Thus, they are suitable for intensity assessment in combination with damage-based intensity scales but can be used as an independent tool, especially in uninhabited areas and for paleoseismic events. This range of intensity degrees is also a valuable tool in the analysis of well-documented historical earthquakes, refining intensity values in urban areas but mainly filling intensity data gaps among populated zones. Environmental damage typically affects areas ranging from 100 km^2 (VIII) to about $5,000 \text{ km}^2$ (X).

From X to XII: Effects on humans and anthropic structures saturate, while effects on natural environment, especially primary, become dominant and diagnostic for this range of intensity degrees; in fact, several types of

environmental effects do not suffer saturation in this range. Consequently earthquake environmental effects (EEEs) are the most effective tool to evaluate the intensity. As in the previous range of intensities, this one is fully applicable to well-documented historical events and also to paleoevents. Environmental damage can extend over areas ranging from 5,000 to 50,000 km².

Guidelines for the Application of the ESI-07 Scale

The ESI-07 scale might also provide a better estimation for intensity assessments than the traditional intensity scales, because earthquake environmental effects are independent from time (modern, historical, or paleo) and do not depend from the socioeconomic development of the region affected by the seismic event. This is true both:

(A) ***In time***, earthquake environmental effects are comparable for a time window much larger than the period of instrumental record (recent, historic, and paleoseismic events). The instrumental records cover about one century, actually much less, if we consider that the introduction of modern global seismic networks started about 50 years ago. As the impact of an earthquake on the artificial environment depends on the distribution and quality of urban buildings and infrastructures, today the comparison of a contemporary event with a historical one (i.e., seventeenth century A.D.) based only on damage indicators might reflect the level of economy in the study area more than the size of the earthquake. Furthermore, the ESI-07 scale allows the expansion of the temporal extent of earthquake catalogues (Silva et al. 2014). Evidence of surface faulting and secondary effects (i.e., Liquefaction, Landslides, Tsunamis) generated by prehistoric events can be identified via detailed paleoseismic investigations, and pertinent ESI-07 values can be derived and used for a

seismic hazard assessment over a geologic time interval.

(B) ***In different geographic areas***, earthquake environmental effects do not depend on particular socioeconomic conditions or different building practices of the damaged zones. In other words, intensity assessments based on building-damage macroseismic scales are commonly influenced by cultural and technological aspects, which may differ significantly from region to region. The ESI-07 scale is independent from these limitations. Moreover, earthquake-prone areas can be located completely or partially in sparsely populated regions, where the effects on the natural environment might be the only evidence available to estimate intensity.

In particular, the ESI-07 scale complements and/or replaces traditional macroseismic scales in the following aspects:

- (a) For earthquake intensity degrees $\geq X$, when damage-based assessments are extremely difficult because the built environment is virtually totally destroyed (so that any assessment based on it is not significant), while environmental effects are still diagnostic.
- (b) In sparsely populated areas, where man-made structures are absent or rare, so that only the environmental effects allow intensity estimates.
- (c) In paleoseismic analyses, where traditional macroseismic scales are not applicable. Additionally, the ESI-07 scale has an advantage over conventional paleoseismological research (i.e., fault-trenching), since the analysis of secondary environmental effects allows the investigation of earthquake cases where no surface faulting occurs, normally in the lower bound of the scale ($\leq VIII$). These kinds of events are commonly “lost earthquakes” for conventional fault-trenching surveys but source of significant building and environmental damage as illustrated by recent moderate seismic events such as the Lorca 2011 (Spain, 5.2 Mw) or the Emilia-Romagna 2012 (Italy, 6.1 Mw) earthquakes.

Intensity Scale ESI 2007 for Assessing Earthquake Intensities, Table 1 Ranges of surface faulting parameters (primary effects) and typical extent of total area affected by secondary effects for each intensity degree

I_0	Primary effects		Secondary effects
	Surface rupture length	Max surface displacement/deformation	Total area
IV	–	–	–
V	–	–	–
VI		–	$\leq 5 \text{ km}^2$
VII	^a	^a	10 km^2
VIII	$< 1 \text{ km}$	$< 5 \text{ cm}$	100 km^2
IX	$1\text{--}10 \text{ km}$	$5\text{--}40 \text{ cm}$	$1,000 \text{ km}^2$
X	$10\text{--}60 \text{ km}$	$40\text{--}300 \text{ cm}$	$5,000 \text{ km}^2$
XI	$60\text{--}150 \text{ km}$	$300\text{--}700 \text{ cm}$	$10,000 \text{ km}^2$
XII	$> 150 \text{ km}$	$> 700 \text{ cm}$	$> 50,000 \text{ km}^2$

^aLimited surface fault ruptures, 10–100 m long with centimeter-wide offset may occur in volcanic areas, generally associated to very shallow earthquakes (From Michetti et al. (2007))

The ESI-07 scale is an independent tool for intensity assessment. So, it can be used alone when only environmental effects are the diagnostic features present; this is the case when effects on man and man-made structures are too scarce or have saturated an area. Other than these cases, it is advisable to estimate two independent intensity fields, one for damage-based scales and one for ESI-07. Their subsequent comparison and integration, based on an expert's judgment, will lead to the best intensity scenario and the most reliable intensity estimate.

Generally, the epicentral region includes the area where the highest values of intensity are recorded. The epicentral intensity (I_0) is commonly close to, and usually corresponds with, the highest estimated value. Surface faulting parameters and the total spatial distribution of secondary effects (Landslides and/or Liquefactions) are two independent tools for assessing an ESI-07 I_0 , starting from intensity VII (Table 1). Of course, specific care has to be paid when surface faulting parameters are at the boundaries between two different degrees. In this case, the intensity value more consistent with the

characteristics and areal distribution of the secondary effects should be selected. Moreover, in the evaluation of the total area, it is recommended that isolated effects that occurred in the far field are not included. This evaluation also requires expert judgment.

Local intensity is generally evaluated through the description of secondary effects (EEEs) that have occurred in different “sites” included within a specific “locality.” In this way, a locality (i.e., a village, a cliff zone, a particular beach, etc.) may record EEE intensity data from different sites, and the eventual assessment of the local intensity is based on the EEE mean and maximum dimensions. This type of intensity has to be comparable with the corresponding traditional local intensity based on damage. It must be noted that a “locality” can be referred to an inhabited area (a village, a town) but also to natural areas without human settlements. When only primary effects are present, the local evidence of surface faulting in terms of maximum observed displacement may be used. Table 2 provides the diagnostic range of intensity in which primary and secondary EEEs can be recorded. The specific descriptions of EEEs for each intensity degree are given in Appendix 1.

Application of the ESI-07 Scale to Paleoseismic Data

Conventional paleoseismic research is focused on fault-trenching analyses, which involve the excavation of trenches of different dimensions across fault traces evidencing past coseismic surface ruptures. These kinds of analyses are focused on the identification, measurement, quantification, and geochronological dating of key stratigraphic features, indicating past surface faulting events (earthquake horizons). The final purpose is to establish the earthquake history of a fault, the seismic potential or capability to generate strong seismic events, and the evaluation of the recurrence periods of earthquakes along the fault (e.g., McCalpin 2009). Widely used empirical relations (e.g., Wells and Coppersmith 1994) among surface rupture length (SRL), maximum fault displacement (MD), and earthquake

Intensity Scale ESI 2007 for Assessing Earthquake Intensities, Table 2 Diagnostic ranges of intensity degrees for each category of environmental effects

Diagnostic range of intensity degrees of EEEs in the ESI-07 Macroseismic Scale											
Earthquake Environmental effects	IV	V	VI	VII	VIII	IX	X	XI	XII		
Surface Faulting and uplift/subsidence	Absent			VII ^a	VIII						XII
A (HA) Hydrological Anomalies	IV			VII				X			
B (AW) Anomalous Waves/Tsunamis	IV					IX					XII
C (GK) Ground Cracks	IV			X							
D (SM) Slope Movements	IV		X								
E (TR) Tree Shaking	IV				XI						
F (LQ) Liquefactions		V			X						
G (DC) Dust Clouds					VIII					XII	
H (JS) Jumping Stones	Absent					IX					XII

^aFor intensity degree VII, limited surface fault ruptures, tens to hundreds meters long with several centimeter-wide offset may occur essentially associated to very shallow earthquakes in volcanic areas. Green-shaded intensity zones represent “rarely to commonly observed” EEEs at indicated intensity levels. Orange-shaded zones represent intensity levels at which individual EEE types are “characteristic and diagnostic” to assess the intensity (Modified from Michetti et al. (2007))

moment magnitude (M_w) allow the estimation of this seismic size parameter. The application of the ESI-07 scale permits estimating the maximum epicentral intensity (I_0) from this kind of paleoseismic approach (see Table 1).

In zones where surface faulting is absent, the most helpful source of information is multiarchive paleoseismic records provided by a variety of secondary earthquake environmental effects, such as paleoliquefaction features and slope movements considered in the ESI-07 scale, but also lake seismites and speleoseismites. For example, the work of Becker et al. (2005) in the Swiss Alps provides good guidelines in the use of secondary EEEs in paleoseismic research. Accordingly, in a case where multiple paleo-earthquake evidence is available in a zone, integrated paleoseismological research is feasible from different geological archives (slope movements, liquefaction, lake, and cave geological records) to identify the seismic history of the zone. Depending on the size of the earthquake (magnitude), attenuation/amplification effects (intensities), and geographical distribution with

respect to the suspect macroseismic epicenter, a same geological archive may record evidence of a given earthquake but also of repeated events in the zone (e.g., Becker et al. 2005). The mapping and dating of paleoseismic features in different geological archives (EEEs) can provide sufficient information, making possible to apply the ESI-07 scale. In zones where surface faulting occurs, the combination of primary and secondary EEEs may offer the best scenario in order to reconstruct the seismic history of the zone, providing a reliable image of the potential seismic hazard.

Figure 2 illustrates a theoretical scenario for the paleoseismic record of EEEs in which it is possible to identify several paleo-earthquakes by means of the recognition and quantification of primary and secondary effects, allowing one to trace paleoseismic ESI-07 zones. Of course, the recognition and attribution of the observed EEEs in each site to a particular paleo-earthquake should be made on the basis of the geochronological dating of the observed features. For Holocene events, the most suitable dating technique when possible is radiocarbon dating (^{14}C). For lake seismites,

highest if the evidence from different geological archives and different sites is combined. In the absence of fault surface ruptures, the illustrated archives of secondary earthquake environmental effects can be used in a similar way (based on Becker et al. 2005)

effects in seismic hazard and seismic risk analyses. Recently, the emergence of ► [archeoseismology](#) leads to the ability to perform combined archeoseismological and paleoseismological analyses of ancient and historical earthquakes (Reicherter et al. [2009](#); Silva et al. [2011](#)).

Summary

The Environmental Seismic Intensity scale (ESI-07) is a twenty-first-century macroseismic scale based on the analysis of geological and environmental effects caused by the earthquakes. The ESI-07 scale represents a quantification of the natural effects considered in traditional

macroseismic scales such as Mercalli, MCS, MM, and MSK. It can be used alone but preferentially combined with the aforementioned macroseismic scales based on building damage. Some recent macroseismic practices in Europe (EMS-98) do not consider natural effects for intensity assessments, and consequently the application of the ESI-07 scale constitutes a relevant complementary approach. Research on earthquake environmental damage (Earthquake Environmental Effects: EEEs) is of use in populated areas and inhabited zones but also at different time windows, including those covering, instrumental, historical, ancient, and paleoseismic events. These latter effects are beyond range of the traditional macroseismic scales, and thus the ESI-07 constitutes one of the most useful tools to expand conventional seismic catalogues to prehistoric and geologic time scales, improving the knowledge on the seismic history of a region or particular tectonic structure and refine evaluations on recurrence periods. This new macroseismic scale considers both on-fault primary effects caused by surface faulting and uplift and a wide range of off-fault secondary ground effects triggered by seismic ground shaking (ground cracks, slope movements, liquefaction processes, hydrological anomalies, and tsunamis). All these primary and secondary EEEs are able to imprint permanent traces in the geological and geomorphological records, especially from intensities above VII–VIII. The comprehensive analysis of EEEs will allow a parameterization of past earthquakes as well as definition of the overall distribution of associated intensity zones, to be applied to future seismic building codes and seismic hazard analyses.

Appendix 1: Definition of Intensity Degrees of the Environmental Seismic Intensity Scale ESI-2007 (*In “italics” highlighted the diagnostic descriptions for different intensity degrees*)

From Intensities I to III

There are no environmental effects that can be used as diagnostic.

Intensity IV

Largely observed/first unequivocal effects in the environment

Primary effects: absent

Secondary effects

- (a) Rare small variations of the water level in wells and/or of the flow rate of springs are locally recorded, as well as extremely rare small variations of chemical-physical properties of water and turbidity in springs and wells, especially within large karstic spring systems, which appear to be most prone to this phenomenon.
- (b) In closed basins (lakes, even seas), seiches with height not exceeding a few centimeters may develop, commonly observed only by tidal gauges, exceptionally even by naked eye, typically in the far field of strong earthquakes. Anomalous waves are perceived by all people on small boats, few people on larger boats, and most people on the coast. Water in swimming pools swings and may sometimes overflow.
- (c) Hair-thin cracks (millimeter wide) might be occasionally seen where lithology (e.g., loose alluvial deposits, saturated soils) and/or morphology (slopes or ridge crests) are most prone to this phenomenon.
- (d) Exceptionally, rocks may fall and small landslides may be (re)activated, along slopes where the equilibrium is already near the limit state, e.g., steep slopes and cuts, with loose and generally saturated soil.
- (e) Tree limbs shake feebly.

Intensity V

Strong/marginal effects in the environment

Primary effects: absent

Secondary effects

- (a) Rare variations of the water level in wells and/or of the flow rate of springs are locally recorded, as well as small variations of chemical-physical properties of water and turbidity in lakes, springs, and wells.
- (b) In closed basins (lakes, even seas), seiches with height of decimeters may develop,

sometimes noted also by naked eye, typically in the far field of strong earthquakes. Anomalous waves up to several tens of cm high are perceived by all people on boats and on the coast. Water in swimming pools overflows.

- (c) Thin cracks (millimeter wide and several cm up to one meter long) are locally seen where lithology (e.g., loose alluvial deposits, saturated soils) and/or morphology (slopes or ridge crests) are most prone to this phenomenon.
- (d) Rare small rockfalls, rotational landslides, and slump earth flows may take place, along often but not necessarily steep slopes where equilibrium is near the limit state, mainly loose deposits and saturated soil. Underwater landslides may be triggered, which can induce small anomalous waves in coastal areas of sea and lakes.
- (e) Tree limbs and bushes shake slightly, very rare cases of fallen dead limbs and ripe fruit.
- (f) Extremely rare cases are reported of liquefaction (sand boil), small in size and in areas most prone to this phenomenon (highly susceptible, recent, alluvial and coastal deposits, near-surface water table).

Intensity VI

Slightly damaging/modest effects in the environment

Primary effects: absent

Secondary effects

- (a) Significant variations of the water level in wells and/or of the flow rate of springs are locally recorded, as well as small variations of chemical-physical properties of water and turbidity in lakes, springs, and wells.
- (b) Anomalous waves up to many tens of cm high flood in very limited areas nearshore. Water in swimming pools and small ponds and basins overflows.
- (c) *Occasionally, millimeter-centimeter wide and up to several meters long fractures are observed in loose alluvial deposits and/or saturated soils; along steep slopes or river-banks, they can be 1–2 cm wide. A few minor cracks develop in paved (either asphalt or stone) roads.*
- (d) Rockfalls and landslides with volume reaching ca. 10^3 m^3 can take place, especially where equilibrium is near the limit state, e.g., steep slopes and cuts, with loose saturated soil or highly weathered/fractured rocks. Underwater landslides can be triggered, occasionally provoking small anomalous waves in coastal areas of sea and lakes, commonly seen by instrumental records.
- (e) *Trees and bushes shake moderately to strongly; a very few treetops and unstable-dead limbs may break and fall, also depending on species, fruit load, and state of health.*
- (f) *Rare cases are reported of liquefaction (sand boil), small in size and in areas most prone to this phenomenon (highly susceptible, recent, alluvial and coastal deposits, near-surface water table).*

Intensity VII

Damaging/appreciable effects in the environment

Primary effects observed very rarely and almost exclusively in volcanic areas. Limited surface fault ruptures, tens to hundreds of meters long and with centimetric offset, may occur, essentially associated to very shallow earthquakes.

Secondary effects: *The total affected area is in the order of 10 km^2 .*

- (a) Significant temporary variations of the water level in wells and/or of the flow rate of springs are locally recorded. Seldom, small springs may temporarily run dry or appear. Weak variations of chemical-physical properties of water and turbidity in lakes, springs, and wells are locally observed.
- (b) Anomalous waves even higher than a meter may flood limited nearshore areas and damage or wash away objects of variable size. Water overflows from small basins and watercourses.
- (c) *Fractures up to 5–10 cm wide and up to hundred meters long are observed, commonly in loose alluvial deposits and/or saturated soils, rarely in dry sand, sand clay, and clay soil fractures, up to 1 cm wide.*

Centimeter-wide cracks are common in paved (asphalt or stone) roads.

- (d) Scattered landslides occur in prone areas, where equilibrium is unstable (steep slopes of loose/saturated soils), while modest rock-falls are common on steep gorges, cliffs. Their size is sometimes significant (10^3 – 10^5 m³); in dry sand, sand clay, and clay soil, the volumes are usually up to 100 m³. Ruptures, slides, and falls may affect riverbanks and artificial embankments and excavations (e.g., road cuts, quarries) in loose sediment or weathered/fractured rock. Significant underwater landslides can be triggered, provoking anomalous waves in coastal areas of sea and lakes, directly felt by people on boats and ports.
- (e) Trees and bushes shake vigorously, especially in densely forested areas, many limbs, and tops break and fall.
- (f) *Rare cases are reported of liquefaction, with sand boils up to 50 cm in diameter, in areas most prone to this phenomenon (highly susceptible, recent, alluvial and coastal deposits, near-surface water table).*

Intensity VIII

Heavily damaging/extensive effects in the environment

Primary effects: observed rarely

Ground ruptures (surface faulting) may develop, up to several hundred meters long, with offsets not exceeding a few cm, particularly for very shallow focus earthquakes such as those common in volcanic areas. Tectonic subsidence or uplift of the ground surface with maximum values on the order of a few centimeters may occur.

Secondary effects: The total affected area is in the order of 100 km².

- (a) Springs may change, generally temporarily, their flow rate, and/or elevation of outcrop. Some small springs may even run dry. Variations in water level are observed in wells. Weak variations of chemical-physical properties of water, most commonly temperature, may be observed in springs and/or wells.

Water turbidity may appear in closed basins, rivers, wells, and springs. Gas emissions, often sulfureous, are locally observed.

- (b) Anomalous waves up to 1–2 m high flood nearshore areas and may damage or wash away objects of variable size. Erosion and dumping of waste is observed along the beaches, where some bushes and even small weak-rooted trees can be eradicated and drifted away. Water violently overflows from small basins and watercourses.
- (c) *Fractures up to 50 cm wide and up to 100 m long are commonly observed in loose alluvial deposits and/or saturated soils; in rare cases, fractures up to 1 cm can be observed in competent dry rocks. Decimetric cracks common in paved (asphalt or stone) roads as well as small pressure undulations.*
- (d) Small to moderate (10^3 – 10^5 m³) landslides widespread in prone areas; rarely they can occur also on gentle slopes, where equilibrium is unstable (steep slopes of loose/saturated soils, rockfalls on steep gorges, coastal cliffs); their size is sometimes large (10^5 – 10^6 m³). Landslides can occasionally dam narrow valleys causing temporary or even permanent lakes. Ruptures, slides, and falls affect riverbanks and artificial embankments and excavations (e.g., road cuts, quarries) in loose sediment or weathered/fractured rock. Frequent occurrence of landslides under the sea level in coastal areas.
- (e) *Trees shake vigorously; branches may break and fall, even uprooted trees, especially along steep slopes.*
- (f) *Liquefaction may be frequent in the epicentral area, depending on local conditions; sand boils up to ca. 1 m in diameter; apparent water fountains in still waters; localized lateral spreading and settlements (subsidence up to ca. 30 cm), with fissuring parallel to waterfront areas (riverbanks, lakes, canals, seashores).*
- (g) *In dry areas, dust clouds may rise from the ground in the epicentral area.*
- (h) Stones and even small boulders and tree trunks may be thrown in the air, leaving typical imprints in soft soil.

Intensity IX

Destructive/effects in the environment are a widespread source of considerable hazard and become important for intensity assessment.

Primary effects: observed commonly

Ground ruptures (surface faulting) develop, up to a few km long, with offsets generally in the order of several cm. Tectonic subsidence or uplift of the ground surface with maximum values in the order of a few decimeters may occur.

Secondary effects: The total affected area is in the order of 1,000 km².

- (a) *Springs can change, generally temporarily, their flow rate and/or location to a considerable extent. Some modest springs may even run dry. Temporary variations of water level are commonly observed in wells. Water temperature often changes in springs and/or wells. Variations of chemical-physical properties of water, most commonly temperature, are observed in springs and/or wells. Water turbidity is common in closed basins, rivers, wells, and springs. Gas emissions, often sulfurous, are observed, and bushes and grass near emission zones may burn.*
- (b) *Meters high waves develop in still and running waters. In flood plains, water streams may even change their course, also because of land subsidence. Small basins may appear or be emptied. Depending on shape of sea bottom and coastline, dangerous tsunamis may reach the shores with run-ups of up to several meters flooding wide areas. Wide-spread erosion and dumping of waste is observed along the beaches, where bushes and trees can be eradicated and drifted away.*
- (c) *Fractures up to 100 cm wide and up to 100 m long are commonly observed in loose alluvial deposits and/or saturated soils; in competent rocks, they can reach up to 10 cm. Significant cracks common in paved (asphalt or stone) roads, as well as small pressure undulations.*
- (d) *Landslides are widespread in prone areas and also on gentle slopes; where equilibrium is unstable (steep slopes of loose/saturated soils; rockfalls on steep gorges, coastal cliffs), their size is frequently large (10^5 m^3),*

sometimes very large (10^6 m^3). Landslides can dam narrow valleys causing temporary or even permanent lakes. Riverbanks, artificial embankments, and excavations (e.g., road cuts, quarries) frequently collapse. Frequent large landslides under the sea level in coastal areas.

- (e) *Trees shake vigorously; branches and thin tree trunks frequently break and fall. Some trees might be uprooted and fall, especially along steep slopes.*
- (f) *Liquefaction and water upsurge are frequent; sand boils up to 3 m in diameter; apparent water fountains in still waters; frequent lateral spreading and settlements (subsidence of more than ca. 30 cm), with fissuring parallel to waterfront areas (riverbanks, lakes, canals, seashores).*
- (g) *In dry areas, dust clouds commonly rise from the ground.*
- (h) *Small boulders and tree trunks may be thrown in the air and move away from their site for meters, also depending on slope angle and roundness, leaving typical imprints in soft soil.*

Intensity X

Very destructive/effects on the environment become a leading source of hazard and are critical for intensity assessment.

Primary effects become leading.

Surface faulting can extend for few tens of km, with offsets from tens of cm up to a few meters. Gravity grabens and elongated depressions develop; for very shallow focus, earthquakes in volcanic areas rupture lengths might be much lower. Tectonic subsidence or uplift of the ground surface with maximum values in the order of few meters may occur.

Secondary effects: The total affected area is in the order of 5,000 km².

- (a) *Many springs significantly change their flow rate and/or elevation of outcrop. Some springs may run temporarily or even permanently dry. Temporary variations of water level are commonly observed in wells. Even strong variations of chemical-physical*

properties of water, most commonly temperature, are observed in springs and/or wells. Often water becomes very muddy in even large basins, rivers, wells, and springs. Gas emissions, often sulfurous, are observed, and bushes and grass near emission zones may burn.

- (b) *Meters high waves develop in even big lakes and rivers, which overflow from their beds. In flood plains, rivers may change their course, temporarily or even permanently, also because of widespread land subsidence. Basins may appear or be emptied. Depending on the shape of sea bottom and coastline, tsunamis may reach the shores with run-ups exceeding 5 m flooding flat areas for thousands of meters inland. Small boulders can be dragged for many meters. Widespread deep erosion is observed along the shores, with noteworthy changes of the coastline profile. Trees nearshore are eradicated and drifted away.*
- (c) *Open ground cracks up to more than 1 m wide and up to 100 m long are frequent, mainly in loose alluvial deposits and/or saturated soils; in competent rocks they can reach several decimeters. Wide cracks develop in paved (asphalt or stone) roads, as well as pressure undulations.*
- (d) *Large landslides and rockfalls ($>10^5$ – 10^6 m³) are frequent, practically regardless of equilibrium state of the slopes, causing temporary or permanent barrier lakes. Riverbanks, artificial embankments, and sides of excavations typically collapse. Levees and earth dams may even incur serious damage. Frequent large landslides under the sea level in coastal areas.*
- (e) *Trees shake vigorously; many branches and tree trunks break and fall. Some trees might be uprooted and fall.*
- (f) *Liquefaction, with water upsurge and soil compaction, may change the aspect of wide zones; sand volcanoes even more than 6 m in diameter; vertical subsidence even >1 m; large and long fissures due to lateral spreading are common.*
- (g) *In dry areas, dust clouds may rise from the ground.*
- (h) *Boulders (diameter in excess of 2–3 m) can be thrown in the air and move away from their site for hundreds of meters down even gentle slopes, leaving typical imprints in soil.*

Intensity XI

Devastating/effects on the environment become decisive for intensity assessment, due to saturation of structural damage.

Primary effects: dominant

Surface faulting extends from several tens of km up to more than 100 km, accompanied by offsets reaching several meters. Gravity graben, elongated depressions, and pressure ridges develop. Drainage lines can be seriously offset. Tectonic subsidence or uplift of the ground surface with maximum values in the order of numerous meters may occur.

Secondary effects: The total affected area is in the order of 10,000 km².

- (a) *Many springs significantly change their flow rate and/or elevation of outcrop. Many springs may run temporarily or even permanently dry. Temporary or permanent variations of water level are generally observed in wells. Even strong variations of chemical-physical properties of water, most commonly temperature, are observed in springs and/or wells. Often water becomes very muddy in even large basins, rivers, wells, and springs. Gas emissions, often sulfurous, are observed, and bushes and grass near emission zones may burn.*
- (b) *Large waves develop in big lakes and rivers, which overflow from their beds. In flood plains, rivers can change their course, temporarily or even permanently, also because of widespread land subsidence and landsliding. Basins may appear or be emptied. Depending on shape of sea bottom and coastline, tsunamis may reach the shores with run-ups reaching 15 m and more devastating flat areas for kilometers inland. Even meter-sized boulders can be dragged for long distances. Widespread deep erosion is observed along the shores, with noteworthy changes of the coastal morphology. Trees nearshore are eradicated and drifted away.*

- (c) Open ground cracks up to several meters wide are very frequent, mainly in loose alluvial deposits and/or saturated soils. In competent rocks, they can reach 1 m. Very wide cracks develop in paved (asphalt or stone) roads, as well as large pressure undulations.
- (d) *Large landslides and rockfalls ($>10^5$ – 10^6 m³) are frequent, practically regardless to equilibrium state of the slopes, causing many temporary or permanent barrier lakes. Riverbanks, artificial embankments, and sides of excavations typically collapse. Levees and earth dams incur serious damage. Significant landslides can occur at 200–300 km distance from the epicenter. Frequent large landslides under the sea level in coastal areas.*
- (e) *Trees shake vigorously; many branches and tree trunks break and fall. Many trees are uprooted and fall.*
- (f) *Liquefaction changes the aspect of extensive zones of lowland, determining vertical subsidence possibly exceeding several meters, numerous large sand volcanoes, and severe lateral spreading features.*
- (g) In dry areas, dust clouds arise from the ground.
- (h) *Big boulders (diameter of several meters) can be thrown in the air and move away from their site for long distances down even gentle slopes, leaving typical imprints in soil.*

Intensity XII

Completely devastating/effects in the environment are the only tool for intensity assessment.

Primary effects: dominant

Surface faulting is at least few hundreds of km long, accompanied by offsets reaching several tens of meters. Gravity graben, elongated depressions, and pressure ridges develop. Drainage lines can be seriously offset. Landscape and geomorphological changes induced by primary effects can attain extraordinary extent and size (typical examples are the uplift or subsidence of coastlines by several meters, appearance or disappearance from sight of significant landscape elements, rivers changing course, origination of waterfalls, formation or disappearance of lakes).

Secondary effects: The total affected area is in the order of 50,000 km² and more.

- (a) Many springs significantly change their flow rate and/or elevation of outcrop. Temporary or permanent variations of water level are generally observed in wells. Many springs and wells may run temporarily or even permanently dry. Strong variations of chemical-physical properties of water, most commonly temperature, are observed in springs and/or wells. Water becomes very muddy in even large basins, rivers, wells, and springs. Gas emissions, often sulfurous, are observed, and bushes and grass near emission zones may burn.
- (b) *Giant waves develop in lakes and rivers, which overflow from their beds. In flood plains, rivers change their course and even their flow direction, temporarily or even permanently, also because of widespread land subsidence and landsliding. Large basins may appear or be emptied. Depending on the shape of sea bottom and coastline, tsunamis may reach the shores with run-ups of several tens of meters devastating flat areas for many kilometers inland. Big boulders can be dragged for long distances. Widespread deep erosion is observed along the shores, with outstanding changes of the coastal morphology. Many trees are eradicated and drifted away. All boats are tore from their moorings and swept away or carried onshore even for long distances. All people outdoor are swept away.*
- (c) Ground open cracks are very frequent, up to one meter or more wide in the bedrock, up to more than 10 m wide in loose alluvial deposits and/or saturated soils. These may extend up to several kilometers in length.
- (d) *Large landslides and rockfalls ($>10^5$ – 10^6 m³) are frequent, practically regardless to equilibrium state of the slopes, causing many temporary or permanent barrier lakes. Riverbanks, artificial embankments, and sides of excavations typically collapse. Levees and earth dams incur serious damage. Significant landslides can occur at more than*

200–300 km distance from the epicenter. Frequent very large landslides under the sea level in coastal areas

- (e) Trees shake vigorously; many branches and tree trunks break and fall. Many trees are uprooted and fall.
- (f) *Liquefaction occurs over large areas and changes the morphology of extensive flat zones, determining vertical subsidence exceeding several meters, widespread large sand volcanoes, and extensive severe lateral spreading features.*
- (g) In dry areas, dust clouds arise from the ground.
- (h) *Also very big boulders can be thrown in the air and move for long distances even down very gentle slopes, leaving typical imprints in soil.*

Interim Housing Provision Following Earthquake Disaster

Regan Potangaroa
Unitec School of Architecture, Auckland,
New Zealand

Synonyms

Core housing; Housing; Recovery phase; Shelter; Transitional housing

Introduction

The provision of interim housing following an earthquake disaster is important because it is the first substantial community step away from the effects of a sudden and unexpected seismic event and back towards some “normality.”

It is defined as housing that is “short term that can be in place for 1 month to 2 years – preferably on sites close to the damaged housing. (To the extent that displaced residents can remain near their previous homes means that economic impacts are reduced.) Interim housing will be needed because those organizations “donating” temporary shelter space need to reclaim that space for its original uses as schools – community centers – churches – that serve the community.” (ABAG 2008).

The idea of “shelter in place” is important not only from a psychosocial perspective of those affected but moreover as part of the subsequent recovery and reconstruction. Shelter in place will encourage local businesses to stay; allow families to return to local schools, friends, social networks, and places; and allow for the restoration of infrastructure based on known numbers rather than estimates or “best guesses.” Thus, it can be the trigger for an early resilient community and city wide recovery.

Interim housing will involve strategic planning and the allocation and use of significant resources, but it is the processes and priorities to be used that have been identified as “problematic” (EERI 2004; Davidson et al. 2007; Johnson 2007; Giovinazzi and Stevenson 2012).

Some of these processes and priorities are evidenced by the “philosophical-one-liners” associated with the operational side of interim housing such as “community engagement” (discussed by Davidson et al. above), “build back better” (Lyons et al. 2010), the notion of disasters as “opportunities,” and of a “one size fits all” or “cookie cutter” housing solutions (Jha et al. 2010). There are several rights-based issues relating to housing land and property that emerge post disaster (IASC 2011), and there are philosophic positions such as the “do no harm principle” (Shelter Cluster 2014) and the “low-hanging fruit” approach where you assist those that are easiest first rather than those based on need. All balanced against the SPHERE standards in humanitarian assistance (SPHERE 2011) or National codes and the political positions of Government departments in developed economies. These all serve to underline its importance but

also suggest a complexity that goes beyond “business as usual.”

The provision of interim housing following an earthquake has several similarities to other fast onset disasters such as typhoons and flooding (Johnson 2002). However, the seismic design and detailing of buildings seems to demand greater technical skills, and as noted by da Silva following the Asian Tsunami disaster in Banda Aceh, Indonesia (da Silva 2010), “. . . a key issue was confusion as to what codes and standards should be followed. . . . Several agencies complied with the Building Code for Aceh assuming that it was sufficient or that local designers and contractors knew what they were doing without realising that safe construction practices were not common practice. Local engineering consultants employed by implementing agencies to develop structural designs generally had limited experience of seismic design, which typically requires an additional post-graduate qualification. This resulted in poor design solutions which were not compliant with the Indonesian code. Recognising this, some agencies employed specialist International consultants or firms to develop or check designs, or sought advice from local and national universities. International engineers were also employed as consultants in-house. However, many of these engineers did not previously have seismic design experience and so were ascending a learning curve, trying to follow available guidance and incorporate it into the construction drawings.”

This still remains an area of confusion for aid agencies (Potangaroa 2010a); and is highlighted in the later case studies.

So how does a building professional survive, let alone remain operationally focused in such an environment? This section considers some of the theoretical context to interim housing and then discusses several case studies from recent earthquakes through the following “lens” (adapted from Davis 2010):

- Planning strategy
- Cost
- Connection to subsequent stages
- The meaning of place

Interim Housing Provision Following Earthquake Disaster, Fig. 1 Examples of interim housing after an earthquake disaster

- Seismic design
- Climatic design
- Community engagement

It then comes back to consider the potential role of building professionals in the provision of interim housing.

Background

The provision of interim housing following an earthquake seems to have the following patterns (Quarantelli 1995) or phases (MCDem 2004) as shown below in Table 1.

The above patterns are perhaps indicative of the operational level of shelter/housing provision, while the phases are more policy and strategic. And, for example, the response phase also includes rapid shelter assessments to

ascertain the “what,” the “where,” and the “who” (the so-called 3W analysis) so that any later housing assistance (including interim housing) can be more effective, can be better targeted, and have a level of accountability; all of which must be updated as the earthquake disaster response and reconstruction develops.

The recovery phase also prioritizes the economic impacts and the apparent need to get businesses back up and running. But as noted earlier, the decisions around housing and where people will stay should preempt such a priority; otherwise, there may not be an available “local” market or the required work force, whether a business has local or national markets.

The word coordination is increasingly used, but the dilemma of the recovery phase (and possibly the provision of interim housing) has been well framed by the Natural Hazards Center comments “How does one make a holistic disaster

Interim Housing Provision Following Earthquake Disaster, Table 1 The patterns and phases of interim housing following an earthquake disaster

Pattern	Measured in . . .	Objectives and locations	Phase
Spontaneous shelter ^a	Days	To provide an interim, safe haven while the situation stabilizes. This could be a school, church/mosque, stadium, park, community hall, or other public facility. Sometimes referred to as evacuation centers. It could also be the home of a friend or family member. It is often on the site of the original house such as in a self-built shelter made from debris material, a camping or basic tent, the garage, or in an undamaged part of the house. There is no outside aid such as food or shelter materials at this point	Response
Emergency or temporary shelter ^a	Months	To provide emergency shelter and contact points for Government and aid agencies supplying food, shelter materials, water, medical/health, and basic supplies such as soaps, blankets, etc. It can be a tent, a larger self-built shelter than before, a public facility, the home of family or friends, hotel, camping ground, park, or a second home. The length varies but will determine the scale of assistance and services required	Response
Interim housing ^a	Years	To provide safe and secure shelter/housing, water, and electricity so that some resumption of family life can be achieved, while efforts are under way to determine and construct permanent, sustainable housing options. This may involve repairs to original housing, the construction of new dwellings, insurance determinations, or relocation options or to find other suitable permanent housing. This can be a prefabricated temporary house, specifically built barracks, camp or motor camp area, a winterized tent, a self-built shelter, a mobile home, an apartment, or the home of family member or friend: using either a transitional or core design approach	Recovery
Permanent housing ^a	Generations	To provide long-term, permanent housing solutions for those affected. This is usually on the original house site but can be within or nearby the community. A final option would be to relocate out of the original community, and this is particularly so where other long-term services such as education/schools are required	Reconstruction

^aThe resumption of family activities is noted as the difference between shelter and housing, and where possible, the difference is noted in the text

recovery happen? How can a decision maker reshape a process that operates within an emotional, reactionary, time-sensitive, expensive, and politically charged atmosphere that is based upon incomplete information, disproportionate needs, and the worst working conditions imaginable?” (Natural Hazards Center 2001).

Davis is more specific with his comments “Finally, a question that arises in the early stages of almost every recovery programme is whether reconstruction and the wider aspects of community rehabilitation should be conducted in the same, original, disaster-prone location, or

whether the population should be encouraged or required to relocate to a new and possibly less vulnerable location.”(Davis 2007).

And it is against this background that the provision of interim housing occurs.

But it gets worse. Strangely, it is not clear who is responsible for interim housing. In a developed economy, the response phase shelter is usually taken up by the Red Cross (ARC 2012), civil society, NGOs, and faith-based organizations, but it is not completely clear who is then responsible for any subsequent interim housing in the recovery phase. Governments do set up specific

commissions, but the basis and objectives of them have been historically questioned (Hewitt 2013). This disconnection was evident in case studies 2 and 3.

A similar situation exists in developing countries and with humanitarian assistance under a cluster approach (OCHA 2012) where the response phase (tents and tarpaulins) would be taken up by the Emergency Shelter and Non-Food Items (NFI) Cluster led by either the International Federation of Red Cross and Red Crescent Societies (IFRC) for natural disasters or United Nations High Commissioner for Refugees (UNHCR) in conflict-based situations. However, the interim housing is subsequently spread across the two clusters of early recovery and camp management and is potentially involved in the WASH (water, sanitation, and hygiene promotion), Protection, and Early Education clusters. Interim housing is essentially an “orphan.”

Timelines for Interim Housing

The time it takes to provide interim housing is often/always underestimated, but that should not be the case. A model developed in the 1970s by Haas suggests the following (Haas et al. 1977):

- If the time it takes to complete the response phase is 1, then:
- The recovery phase will be 10 times.
- The reconstruction phase will be 100 times.

These are approximations, and there are certainly difficulties in ascertaining when the response phase is actually complete. But as reported by Zuo, the approach is widely accepted and quoted which he details (Zuo 2010). It does provide a useful operational and planning base that is firstly “sobering” but also one that secondly better reflects the actual times (rather than the planned ones) allowed for earthquake disaster responses.

For example, the 22 Feb 2011 Christchurch Earthquake based on a response time of around 3 months would suggest the following timeline:

- Response phase of 3 months: 22 February 2011 to 22 May 2011

- Recovery phase of 30 months: May 2011 to November 2013
- Reconstruction phase of 300 months: November 2013 to November 2037.

This timeline would be difficult for any public authority or the Government to acknowledge and especially present to its electorate. The result is the conviction that all must be OK and a filtering of information to make it fit. Consequently, the Government is communicating exactly that message, that all is well and under control. On one hand, a local respected NGO called CanCERNs has initiated the 900 Project to identify what they suspect are the remaining 900 uninhabitable houses in Christchurch 3+ years after the earthquake and hence possibly out of control (CanCERN 2014).

Such timelines suggested by Haas are unfortunately ignored by Governments and aid agencies for various reasons (Lloyd-Jones 2006). However, on the flip side, it does suggest that any reduction of the response phase will have huge reductions for the subsequent recovery and reconstruction phases. Therefore, the planning and implementation of interim housing should start immediately and not wait till after the response phase has been completed. This “lesson learnt” seems to be repeated in subsequent seismic disasters.

Costs of Interim Housing

Typically, the costs for interim housing can be comparable or at least significant against the cost of permanent housing. For this reason, attempts have been made to miss out the interim housing and go more directly to permanent housing (as in the Banda Aceh case study). Alternatively, humanitarian and aid agencies have developed transitional and core housing approaches that uses any interim house as part of a permanent housing development thus “saving” on overall cost. There are additional political and planning reasons for this approach as it allows for more permanent outcomes for those affected based on an apparent interim solution which is politically expedient when those being assisted may be settled informally and do not have any formal land

title and have been that way for some time before the earthquake.

Transitional and Core Approaches to Interim Housing

Transitional housing is where an interim house is designed to merge into a permanent one. This usually means that the structural system (and in particular the lateral load resisting part) is retained and the cladding usually changed over time. This in part seeks to save overall housing costs but more importantly to minimize the emotional impacts on families having to relocate, yet again. It can also make the shelter-in-place option more viable though it has been used in off-site as a prefabricated kitset that goes with the occupants. However, its big advance is that the occupants can upgrade as money and resources become available, and perhaps other family needs arise that require more space such as births and marriages. Typically, the transitional house could be supplied clad in plastic tarpaulins, which can be later replaced with mud bricks, mud-plastered stone, or cement-plastered concrete blocks. The design trick is to structurally ensure that the lateral load resisting as supplied has sufficient capacity for this anticipated loading of a heavier cladding.

A core house on the other hand is where some part of a permanent house is supplied which is then added and extended over time as money and resources become available.

The objective of both approaches is to “transition” the family/occupants into a more permanent or “durable” housing solution based on their priorities (rather than the aid agency) under their own direction. Such approaches are more readily found with aid agencies and in developing economies rather than Governments and developed economies despite their appropriateness for both.

Codes and Planning for Interim Housing

The level and criteria for code compliance for interim housing in post-earthquake situations are contentious. On one hand is whether there should be any/minimal code and planning compliance given the urgency of the need, the

temporaryness of the building, and the often dire living conditions of those affected, while on the other hand, the ongoing seismic activity, the relative expense of the interim house, and its possibly semi-permanence suggest that it fully complies with the stipulated country and possibly international codes. Moreover, if these are being done in large numbers (rather than as a one off), it seems to support full code compliance. There is also the issue of their disposal once they have done their job. This can be more difficult than expected (Arslan and Coşgun 2007).

Most developed economies do not have specific codes or planning procedures for interim housing, and because it usually occurs outside, any declared state of emergency will often require some type of executive order. In Christchurch, for example, specific guidance notes were compiled to facilitate the compliance and provision of post-disaster worker accommodation (MBIE 2012). FEMA on the other hand has a suite of interim house types that it can use (DHS 2013) which have had issues in the past and would be pushed to respond in a timely manner to a disaster (McIntosh 2013). There are various guidelines for short-term/interim housing for the military, for farm workers, and for the homeless (USAF 2001; QG 2010; SAMB 2009; Wilson 2013). Strangely, there is minimal design code or guidance post disaster and seemingly nothing that specifies the roles and responsibilities of local authorities or Government in terms of interim housing of affected people.

Moreover, the issue for the worker accommodation built in Christchurch will be what happens to them when they reach their use by date of 31 December 2022. Will the worker’s accommodation be demolished or simply on sold possibly creating substandard long-term housing somewhere else? Or will the date simply be extended?

In developing economies and the humanitarian aid sector, there are two “codes of compliance.” In a refugee situation, it is the UNHCR’s Handbook (UNHCR 2007), while in natural disasters, it is SPHERE (2011).

The UNHCR Handbook was developed from experience in the field and was widely accepted as the de facto standard and code even outside the

refugee situation. However, its “camp” focus meant that it increasingly did not translate well into non-refugee situations. And hence the SPHERE Project was initiated to set up universal minimum standards in core areas of humanitarian response. A lack of such standards has in the past resulted in “competition” between shelter agencies. Though it was started in 1997 (with the first trial edition in 1998), the shelter response in Banda Aceh after the 2004 Asian Tsunami is often remembered because of the competition that developed. Shelter options were seemingly raked up with one agency offering a house, then another offering a house and \$2,000USD, and the next a house fully furnished and later with an opening party for friends.

The size and specifications of temporary shelter also generated unintentional competition between shelter agencies, and, for example, the “China tent” in Pakistan following the 2005 Kashmir Earthquake was the “tent of choice” firstly because it had walls which meant that one could stand up anywhere inside it but secondly because it had a steel frame which performed better under snow loading. SPHERE has been revised in 2000, 2004, and in the current green-colored version of 2011. The key quantitative shelter points are the following:

- Site slope should neither exceed 5 %, unless extensive drainage and erosion control measures are taken, nor be less than 1 % to provide for adequate drainage. The lowest point of the site should be not less than 3 m above the estimated maximum level of the water table.
- There should be a minimum usable surface area of 45 m² for each person when including household plots/gardens or 30 m² otherwise. And where this cannot be provided, the consequences of higher-density occupation should be mitigated, for example, through ensuring adequate separation and privacy between individual households, space for the required facilities, etc.
- There should be a 30 m firebreak for every 300 m of built-up area and a minimum of 2 m (but preferably twice the overall height of any structure) between individual buildings or

shelters to prevent collapsing structures from touching adjacent buildings.

- In cold climates, household activities typically take place within the covered area, and affected populations may spend substantial time inside to ensure adequate thermal comfort. In urban settings, household activities typically occur within the covered area as there is usually less adjacent external space that can be used.
- A covered floor area in excess of 3.5 m² per person will often be required to meet these considerations.
- The internal floor-to-ceiling height should be a minimum of 2 m at the highest point. In warmer climates, the adjacent shaded external space can be used for food preparation and cooking. Where materials for a complete shelter cannot be provided, roofing materials to provide the minimum covered area should be prioritized. The resulting enclosure may not provide the necessary protection from the climate nor security, privacy, and dignity, so steps should be taken to meet these needs as soon as possible.
- Standards and guidelines on construction should be agreed with the relevant authorities to ensure that key safety and performance requirements are met. Where applicable local or national building codes have not been customarily adhered to or enforced, incremental compliance should be agreed, reflecting local housing culture, climatic conditions, resources, building and maintenance capacities, accessibility, and affordability.

These have been included because of an otherwise scarcity of guidelines.

Interim Housing and Diversity

The standardized nature of interim housing can miss out the special needs of sections of an affected population. These can include pregnant and lactating mothers, the elderly, the blind, the wheel chair bound, the bed ridden, single parent families, and those with medical or mental challenges. It can also happen in unexpected areas. For example, it was unfortunate that a Maori

family with previous gang ties was evicted from an evacuation center following the September 2010 earthquake in Christchurch (Kipa et al. 2013). This exclusion leads to the setting up of a specific Maori response when the February 2011 earthquake occurred 5 months later. The notion that New Zealand society could be fractured like this still remains deep, as it no doubt does for the Lower 9th Wards of New Orleans.

Such people are essentially invisible in a disaster, and there is a reliance on self-identifying. The sudden nature of earthquakes means that self-identification before the event is at best limited. As a result, such issues only surface (unfortunately) around the provision of interim housing, and their special needs were compounded by that time by the loss of vital connections with personal care providers and sources for medication, service animals, community liaisons, public transportation, neighbors, and their network of contacts. And the diversity challenge is whether the provision of interim housing addresses a diverse community in an inclusive manner. This is not easy or straightforward, and failures are not recorded because they are seen as failures of the wider community or society such as the above example.

Case Study 1: Sichuan, China, 2008

Seismic event: 12 May 2008, magnitude 8.0.

Deaths: 69,195 deaths and 18,392 missing (Wikipedia 2008).

People affected: the earthquake left about 4.8 million people homeless, though the number could be as high as 11 million.

Total amount of direct damage: 845.1 billion RMD (137 billion USD) (UNCRD 2008, p. 5).

Disasters of this scale are not uncommon in China, and interestingly, this was the first time that China allowed foreigners into a disaster zone (perhaps because it was hosting the Olympics in Beijing later that same year in August), and hence for many, it was a unique opportunity to observe how the Chinese disaster response works. The two key aspects relevant to interim housing seem to be their community (or village)-based

approach and partnering. This allowed the construction of around 500,000 temporary houses in 3 months following the earthquake and was one of the best disaster responses measured by the well-being of affected families (Potangaroa et al. 2009). The temporary homes or shelters had a floor area of 20 m² and were designed for three people (EERI 2008).

On 6 June 2008 (3 weeks after the disaster) the State Council published the Wenchuan Earthquake Restoration and Reconstruction Regulations and provided legal guidance for the formulation of the overall reconstruction plan (Kristin et al. 2012). The plan emphasized restoring residential housing and in particular the need for addressing the differences of multistory urban apartment blocks and low-rise rural housing. The plan also laid out the process to be adopted which consisted of the three following actions:

- Survey and assessment
- Plan drafting
- Policy measures

In response to this, the Sichuan Provincial Government published in that same month of June the “Sichuan Rural Housing Reconstruction Plan” and then in September the “Urban Housing Reconstruction Plan,” while the Central Government published the “Sichuan Rural Housing Repair and Reinforcement Plan” in December 2008.

These plans laid out six methods for reconstructing or replacing houses that were damaged in the earthquake, namely:

- Reinforcing the house
- Rebuilding the house on the original land
- Rebuilding the house on replacement land
- Renting a low-cost house
- Buying a low-cost house
- Rebuilding the house organized by “workplaces”

There were additional options in urban areas of buying a low-cost house, renting public housing, or receiving a cash subsidy.

Houses were assessed and classified according to the extent of damage into the following five categories:

- No damage
- Minor damage
- Medium damage
- Serious damage
- Collapse

Apart from houses that had “collapsed” or had sustained “no damage,” categories would receive a cash subsidy of 1,000–2,000 (\$163–\$325), 2,000–4,000 (\$325–\$650), or 4,000–5,000 (\$650–\$813) RMD (\$USD), respectively. Urban households whose houses had collapsed or were inhabitable could receive a cash subsidy, a housing tax exemption or reduction, and preferential low-cost housing. The average cash subsidy was 25,000 RMD (\$4,066USD) depending on the household’s size and economic status.

In rural areas, many houses were rebuilt on different land, and in these cases, the town and village authorities could choose to rebuild the houses collectively, with each household contributing a share. The point to note is that the whole village was relocated and not individual families. Households were entitled to a cash subsidy of RMD 20,000 (\$3,250USD) (on average) to rebuild with the exact amount determined by the number of people and their overall economic situation. Households that decided on an alternative living arrangement such as living with other family received a reduced subsidy of RMD 2,000 (\$325USD).

In October 2008, the Sichuan Government announced various preferential loan policies for households to rebuild their house or buy a new house. For households taking out a bank loan to purchase a new house, the minimum interest rate was adjusted to 0.6 of the benchmark lending interest rate, and the minimum down payment was reduced to 10 %. And for rebuilding, buying or strengthening a house received a 1 % point discount on their interest rate.

Where ever possible, communities are relocated as a community or village, and not individually (UNCRD 2008, pp. 22–24). Each

village has its own organizational structure that interfaces between the people of the village and the city authority. This provided a ready two-way information conduit with assessment and damage data being fed up and strategy and priorities being fed down. Thus, the authorities had rapid and relatively accurate data very early and hence could plan an appropriate response. This included a partnering or “twinning” arrangement whereby affected cities and towns are linked to other cities and towns in China who are then expected to assist. The partnering arrangement can be competitive as results from it are published by the Central Government. But this could also be because the workers from coastal cities working in the mountainous and colder regions of Sichuan and staying in tents and their own cars perhaps feel more motivated to get the work completed quickly.

However, despite its important role in terms of financial and resource allocation, it does seem to have three areas of concern (UNCRD 2008, p. 5):

- Variation in support from provinces.
- Inappropriate support that may not necessarily reflect the needs of a different climate, culture, and social background of the partner region. For example, facilities provided from Northern Provinces had double-panel windows and contain heat-insulating materials, while those provided from Southern Provinces have no such equipment. This is not a big problem in the phases and rescue and rehabilitation because short-term responses or restoration is required in the phases. In the reconstruction phase, however, supporting materials need to be accepted by the supported region.
- Supporting provinces tend to have a larger voice and decision-making power than supported areas.

Summary

It has been historically difficult getting access to disasters in China, and certainly while access was granted to foreigners following the earthquake in Sichuan, it was nonetheless limited and understandably constrained. Thus, reports and feedback from the field are scarce. This is a pity as

the scale and response to seismic disasters has much that other countries could learn from and adapt for their own situations. The partnering approach and the speed at which interim housing was achieved are two clear examples. While it was conceivably possible for the Government to impose price controls, this did not seem to happen during the four field trips made by the author and several others made by PhD students studying aspects outside the provision of interim housing (Chang et al. 2011). Moreover, the use of loans and other seemingly market instruments to manage the response perhaps suggested a sophistication beyond simply Government structures.

Case Study 2: Port-au-Prince, Haiti, 2010

Seismic Event: Magnitude 7.0, 12 January, 2010.

Deaths: 220,000 deaths with some variance between different estimates.

People affected: an estimated three million people were affected by the earthquake together with the collapse of 250,000 residences and 30,000 commercial buildings (Ferris 2010) (Wikipedia 2010).

This was the first large-scale humanitarian response involving a “crowded” urban context. The rural response seems to lead the urban one, and the reasons why become clear when people see photographs of the affected area in the capital of Port-au-Prince. The poorer areas effectively are 100 % covered in corrugated iron roofing, and hence, the immediate question was: Where would any interim housing be established? The planned shelter solution was to build on the site of the former house which required demolition and clearing of the site before the interim housing could be erected. Needless to say, this was problematic in itself; the “owners” had to be found, land tenure had to be identified, the rubble had to be typically carried out by hand out to the road, and the interim house had to be built. However, when this was completed, where was any permanent housing to be erected? Consequently, the interim house or T-Shelter took on a more permanent role that it was not intended, and the role of what was intended as a “transitional” house

became increasingly questioned as transition to what?

Nonetheless, providing emergency shelter support to over 1.5 million people in less than 4 months was an outstanding achievement (Rees-Gildea and Moles 2012). The Shelter Cluster’s “harmonized” emergency shelter and NFI response seemed to be a coordination success (the United Nations emergency response consists of 11 sector clusters and one of those is the Shelter Cluster. It is headed by the IFRC for natural disasters and UNHCR in conflict situations). However, the emergency shelter (E-Shelters) response was essentially based on a one-time massive delivery of tarpaulins and tents, there was some variation in quality, but more importantly, there was little or no control over the shelter outcomes that those affected were selecting. Camps both small and large blossomed throughout Port-au-Prince, and at one time, there were over 1,300 camps with 100 people or more. Camps were established in parks, on golf courses, around churches, and on street corners. The shelter agencies did not have the means to guide or direct the final outcome of the E-Shelters. The large numbers and the tight urban situation made it impossible to meet the SPHERE standards such as a minimum of 3.5 m²/person in covered area (such as a tent or tarpaulin), 30 m²/person in camp land area, and the prescribed numbers of toilets and showers. It was hoped that these perhaps could be progressively met as camp numbers decreased. This did not happen as people seemed to “settle” into camp life, and 1 year later, nearly one million people were still in camps.

Replacement of such shelters that have a service life of around 6 months was not initially planned with the intent was to move into T-Shelters by the end of 2010. That did not happen for many reasons, and consequently, there was a shelter gap as the hurricane season rolled in, and another call for replacement tarps and tents was made. This unplanned double effort put more pressure on the overall T-Shelter program and meant a higher workload for shelter agencies together with an unexpected additional budget line. This vulnerability became evident

when a relatively small depression Ivan hit Port-au-Prince destroying 9,000 E-Shelters.

The Shelter Cluster was also seeking to harmonize the T-Shelter in much the same way it had for the E-Shelter. There were several different types developed by aid agencies based around the following standardized criteria (IASC 2010):

- An area of 12–18 m² for a single-story structure
- Cost between \$1,000 and \$1,500USD (including transport and labor) later increased to \$1,800
- Designed for a 100 mph wind load
- Designed for seismic loads
- A 3-year life span but later increased to 15 depending on possible building up grading
- The lack of a diaphragm transfer system. This structural system transfers lateral loads (such as wind and seismic) through the building to vertical structure which takes it to the foundations. It is usually located in a horizontal plane such as the ceiling or roof.
- Foundations and their spatial relationship to the above wall bracing. It was noted that diagonal bracing in walls were not located above foundations and as such would be unintentionally bending and potential breaking the wall bottom plates.
- A lack of gable end bracing. This is where braces are required to prop gable ends back to a horizontal structure.
- Roof slope: pitched roofs were advised to be +30° and mono-sloped roofs 12–14°. This was done to minimize wind up lift loads.

This harmonization proved problematic for several reasons, and as a result, shelter numbers had to be lowered to fit existing budgets. For example, there were no seismic codes and, hence, no seismic zones for Haiti. In addition, the nature of the wind loading was not clear but also not questioned. Was it a 3 s gust or a sustained wind load; what was the specified terrain and at what height was this measured (Potangaroa 2010b). Consequently, agencies and their respective designers in other parts of the world using at times non-hurricane wind loading codes seemed to make their own assumptions of what this wind speed meant. For example, the ASCE 7 code produced basic wind loads of around 1.2 kPa, while the same wind speed in the British code produced a 2.5 kPa loading (it should also be noted that hurricanes are not featured in the British code). This was not apparently picked up by agencies or their designers who invariably were not based in Haiti but were working from information provided by aid agencies in the field. This resulted in significant cost over runs particularly for foundations and costs quickly blew out with the largest being in the order of \$4,500USD, nearly three times over the capped value.

In addition, there were other aspects of concern with the seismic and wind design of the T-Shelter design that included the following:

The 11 exemplar T-Shelters on the Shelter Cluster web page were examined, and these are tabulated below (Table 2).

A lack of a horizontal structure or suitable foundations would constitute a systemic issue, while the gable aspect could/would be more localized. Thus, at least six had systemic issues and nine localized issues, and given that these 11 are probably better examples underlines an issue that aid agencies need to address. This same issue of design is also raised in the Aceh case study that follows. However, aid agencies are usually reluctant to discuss these issues given the large resources and costs involved in the provision of interim housing.

Perhaps this was partly why many agencies “were inclined to work outside Port-Au-Prince, mainly funding the direct delivery of transitional shelter [T-Shelters] and not integrating a housing repair approach into their programmes. . . . This widely supported strategy [T-Shelters] was unrealistic in timing and cost-wise and was not flexible enough. Relevant progress in T-Shelter delivery started by May 2010, and the sum of the agencies capacities (125,000 units) proved to be insufficient to meet total transitional shelter need (over 180,000) within the foreseen timeline (January 2011), even after maximum delivery capacity was reached (7,300 units per month, as

Interim Housing Provision Following Earthquake Disaster, Table 2 T-shelter design aspects

	Horizontal structure	Foundations	Gable brace	Roof slope
Agency 1	No apparent structure	Do not appear to relate to diagonal braces	Partial separation for side gables?	OK
Agency 2	OK diagonal steel ties	OK concrete slab	OK diagonal timber brace	OK
Agency 3	No apparent structure	Do not appear to relate to diagonal braces	OK diagonal timber ties	OK
Agency 4	OK diagonal timber ties	Probably OK concrete block and slab foundations	No apparent brace	OK
Agency 5	OK diagonal timber ties	Probably OK because of external plywood	No apparent brace	OK
Agency 6	No apparent structure	Do not appear to relate to diagonal braces	Full height member but no apparent bracing at roof level	OK
Agency 7	No apparent structure	No apparent bracing?	No apparent brace	Not clear
Agency 8	OK diagonal steel ties	Probably OK because of external plywood	No apparent brace	OK
Agency 9	No apparent structure	Do not appear to relate to diagonal braces	No apparent brace	Less than 30°
Agency 10	OK diagonal timber ties	Probably OK because of concrete ring beam	No apparent brace	Probably OK
Agency 11	OK diagonal steel ties	Do not appear to relate across the building	No apparent brace	OK

of November 2010). All of which led to an accumulated delay, to bottlenecks in the implementation process, and to unforeseen relief responses as new emergencies arose. In addition, the approach of faster delivery of simpler transitional shelter could not be always achieved, and the shelter agencies had serious difficulties in meeting the agreed upon standards and average costs, leading upwards of a 200 % increase in the anticipated costs. . .” (EPYPSA 2011, p. 5).

That report goes on to outline the complexities of supplying transitional shelter with its comments that “The shelter sector in Haiti promoted a return to a neighbourhood strategy aimed at drawing the displaced population out of the camps through the provision of shelter (transitional, permanent, home repairs), but the shelter agencies procrastinated their engagement in housing repair.” This low engagement in housing repair and seismic strengthening may have

been caused by the following (EPYPSA 2011, p. 46):

- Lack of experience and perhaps a fear of the complexity involved (first “urban”-based seismic disaster for the humanitarian agencies with a lack of physical access, emphasis on rubble, problems of logistics, and few trained staff and labor)
- Difficulty to design big-scale funding proposals (each situation was different).
- Budget over runs (unforeseen costs that can only become clear during construction).
- Lack of funding (HQ and/or donors not willing to go into complex construction projects).
- Beneficiary selection and involvement (who and how should assistance be provided?).
- Repair or retrofit? (Repairs would fix the damage but not it’s lack of earthquake capacity. Retrofitting would address both issues but

could be expensive and would require specialist skills)

- Should this be seen as an emergency rather than a recovery/reconstruction response?
- Camp-driven response easier to manage and control (less constraints and higher visibility).
- Overall perceived as “easy to get into, but hard to get out.”

Some agencies such as the IFRC did manage to develop a seismic retrofitting program (Potangaroa et al. 2011b). This approach had the distinct advantage of being well under the \$2,200–2,400USD/family cost to relocate families out of the camps. However, as indicated earlier, this option was developed late in the response in Port-au-Prince because there was the sense that any seismic retrofitting would have to be prohibitively expensive. The approach was based on the following two factors (Potangaroa et al. 2011):

1. An acceptance of higher level of building damage in an earthquake; up to what is often termed “near collapse.” Most seismic codes are based around a “safe exit” strategy which requires a lower level of damage.
2. A realistic determination of the life span of the building. Again most codes are based around approximately 100 years, but the low building quality suggested a 25–30-year life span.

And these two factors allowed for a code compliant design to levels that were appropriate to the building culture of Port-au-Prince rather than a developed one in San Francisco or Wellington.

The seemingly final part of the interim housing in Port-au-Prince was a Government initiative to set a repair program for 16 neighborhoods and to decongest six camps associated with those neighborhoods under a proposed 16-6 Program (IOM 2012). Camp dwellers and residents in damaged neighborhoods could choose between either having their homes fixed or taking a 1-year rental subsidy of \$500USD. About 10,000 families took this option. However, what was going to happen beyond that year was not clear; again it was the “transition to what”?

Summary

The timelines required for interim housing were seemingly underestimated in Port-au-Prince. This caused several issues and, for example, the relevance of the T-Shelter decreased, “while other approaches like repairs, rental subsidies or even permanent housing became relevant and even more cost efficient as time elapsed” (EPYPSA 2011). The affected population also started to look at the T-Shelter as permanent solutions, both because they were of a higher standard than their original housing and because they were unaware of any planned transition. Shelter agencies planned to build 125,000 T-Shelters in 10 months (March 2010 to January 2011) but were unable possibly because the numbers were too ambitious to start off with. With time, material costs escalated, the T-Shelter increased its life span beyond the specified 3 years, and issues such as land tenure, rubble clearance, and urban setting resulted in lengthy delays. Hence, by November 2010, only 19,000 T-Shelters (15 % of the total goal) had been completed and delivered.

Secondly, the role of appropriate structural design was missed by aid agencies. This will be highlighted in the next case study on Banda Aceh. It would seem that this lesson has not been learnt. And while aid agencies may be unnecessarily concerned about design risks and responsibilities, the apparent situation of six systemic and nine localized failures from 11 exemplar T-Shelters in Port-au-Prince would seem to deserve decisive attention from the aid community beyond a concern with design risk and responsibilities. Moreover, there seems to be opportunities to better mainstream the social needs and concerns of communities by a reflective design approach suggested by the IFRC retrofitting approach.

Finally, it would also seem that there is currently no urban game plan for provision of interim housing. While the rural response seemed to be managed in Haiti, the urban one in Port-au-Prince was not. It would seem that the provision of interim shelter in urban areas needs more discussion and research, hopefully before the next earthquake disaster. This is supported by the case study 1 on Christchurch.

Case Study 3: Banda Aceh 2004 and Yogyakarta 2006

Seismic event: Magnitude 9.0, 26 December 2004	Seismic event: Magnitude 5.9, 27 May 2006
Deaths: 130,000 deaths	Deaths: 5,716 deaths
People affected: million houses were destroyed or made uninhabitable	People affected: 240,396 houses were destroyed (IRC 2009)

These two responses were connected firstly because of their geography and timing but also because the Banda Aceh experience is now seen as a kind of watershed for humanitarian agencies working in the interim shelter sector that flowed over into Yogyakarta. The sense at the time of Banda Aceh was to miss out any interim housing and instead go directly to permanent housing (Potangaroa 2006). The Government had indicated that they would build barrack type accommodation and that combined with people returning to their original tsunami affected sites and staying with other family members seemed to be the basis of the Government's strategy. Land tenure was an issue as much of it was oral and informally agreed between male community members. Thus, the loss of land marks and people meant that ownership was no longer certain. In response, agencies put together a multi-program such as the one proposed by UNHCR (Potangaroa 2005):

- New Housing on new or former home sites. (Four sizes of housing proposed depending on family size).
- A "Granny" flat option addition to an existing house where those affected wish to stay long term with other "host" family members (the size was based on the living/lounge area and toilet bathroom areas from a spatial survey of non affected houses in Banda Aceh).
- Shelter Kits for repair of an existing house.

However, in March 2005, the Government suggested that agencies such as UNHCR (and also IOM) should not be in the once military zone of Aceh; thus plans such as the above were

never realized at the scales planned (TIME 2005). This created a strategy and agency vacuum and consequently it was not till September 2005 (9 months after the disaster) that the IFRC launched its Temporary Shelter Plan of Action. This consisted of a 25 m² lightweight bolted steel frame, with timber cladding and a metal roof. The foundations were supposed to be anchored down but usually were leveled and left. Problems with appropriate sustainable timber supplies delayed its release but by December 2005 a prototype was in place. Consequently, many families did not receive these interim/transitional shelter kits until 2006. This interim kit was valuable and on the informal market could be purchased for \$5,000–\$6,000USD. This was also before the advent of the Shelter Cluster approach, and so agencies tended to operate independently and without any coordination.

Da Silva explains that the (da Silva 2010) "Shelter policy was not developed within the overall context of the journey from emergency shelter to durable solutions, and over the first six months there was considerable confusion and no clear policy as to the type of shelter assistance required. In June 2005, BRR [the Government's Disaster Response Agency] announced that families should be encouraged to return to their own land or to voluntarily resettle on land purchased by communities themselves or by BRR. They also stated that each affected household would be eligible for a permanent 36 m² house, with an expectation that this could be realised within a year, in the belief that in the interim affected communities were adequately housed in barracks, transitional shelter or with host families. Agencies who had already constructed 'semi-permanent' houses were faced with having to upgrade or replace housing, as these were no longer deemed adequate. This timeline proved unrealistic and did not reflect the realities on the ground, led to false expectations by the media, donors, government and beneficiaries and placed considerable pressure on implementing agencies."

Consequently, Da Silva's conclusion was that the notion that everyone who was affected should get a house led to a focus on "reconstruction rather than recovery" and an "emphasis on

providing houses rather than assistance to reconstruct.”

One further “lesson” was that agencies needed to have experienced seismic design engineers involved; otherwise, a less than adequate seismic solution could be used. And that having solely civil or structural engineers or local engineering input was no guarantee of finding an appropriate or even adequate seismic solution. Some agencies had again to come back and seismically strengthen the housing they had already constructed. Invariably this relates to “simple” structural detailing such as the spacing of column ties or beam stirrups/links. This was not the common practice amongst local consultants and builders in Aceh. In addition, the Indonesian Seismic Code excluded single-story dwellings, and the building code for Aceh issued by BRR (UNHIC 2005) did not include basic seismic design principles. This resulted in widespread confusion that compounded the view that seismic design would be considerably more expensive. BRR did not enforce the need for seismic design and themselves built houses and schools which did not conform to basic seismic guidelines. Da Silva goes on to report that “...most DEC [Disasters Emergency Committee (UK)] Member Agencies ultimately did adopt seismic design approaches but this was not always matched by quality construction and the design intent was compromised by poor quality materials and workmanship on site. In some cases remedial works and retro-fitting was needed to create a safe structure.”

Agencies tried to dodge these issues with the response in Yogyakarta; but unfortunately repeated many of the same problems.

The Indonesian Government was reported as not being able to cover the need for shelter in Yogyakarta, not simply because of a lack of finances but also due to its scale and that it was much greater than initially believed (Roychansyah 2009). To meet the need for shelter, the Indonesian Government, United Nations agencies, and other humanitarian partners developed a “roof first” interim housing strategy to be implemented from the time aid is first provided up to the stage of community rehabilitation.

The Emergency Shelter Cluster was coordinated by the IFRC who calculated that with an average household size of 4.3 that at least 1,173,742 people, and perhaps as many as 1,542,380 were left homeless by the earthquake. However, the provision of tarpaulins and tents was limited, and by the end of July 2006 (2 months after the earthquake) at the end of the Response Phase, almost 30 % of these numbers were still homeless.

Despite this short fall interim housing was achieved using emergency bamboo and tarpaulins and recycling materials (such as bricks, timber, and window, and door frames), and finally villages that had sustained less than 20 % damage accommodated those made homeless using a kinship family model within the village.

The goal during the response phase was in addition to the usual emergency tents to also provide interim housing or T-Shelter (Setiawan 2007). Most were constructed from bamboo which was selected because of its low cost, availability, and strength. Sizes varied between 18 and 36 m². There were three different levels of community participation with regard to shelters: participation in the design process, participation in contributing materials for transitional shelters, and participation in the construction process (IRP 2009; JRF 2008). Somewhere in these phases, there were two significant structural changes; the first was the inclusion of a heavy clay tile roof for cultural reasons. It seemed that no normal Javanese man would sleep under anything other than a clay tile roof. And secondly, the bamboo wall braces were lifted so that people could readily enter in the side of the interim houses. The clay tile roof rendered the house as earthquake prone, and the movement of the wall braces minimized any remaining seismic resistance. This clash between community engagement and the confusion around seismic standards that was so problematic in Aceh had not been learnt for Yogyakarta or for Haiti.

Summary

The provision of interim shelter is important because it is often the first step towards

normalizing a community following an earthquake. It is perhaps more complicated and certainly takes longer than expected, and the key appears to be the engagement with the affected people. This seems to apply whether it occurs in a developed or developing economy and whether it is provided as aid assistance or not.

The definitions for interim housing given in the literature need to be reviewed. And, for example, the one provided at the start of this chapter of between 1 month and 2 years is probably too soon on both the 1 month and the 2 years for a large-scale disaster or catastrophe.

While affected communities are the key focus for what is needed, Governments are the key influence for how that could be provided. Strangely Government departments (representing the Government) seem to have problems communicating with their affected communities when there is not an existing communication structure prior to the earthquake. Where it does not exist, departments must ensure that what is happening in the field is directly measured and observed rather than remotely from a headquarters/office location.

Interim housing is expensive and can unintentionally become more permanent housing. Its design can be problematic again in both developing and developed economies, and there are gaps for interim housing strategies for urban contexts. It is perhaps sobering to reflect upon Jean Jacques Rousseau's letter to Voltaire after the 1755 Lisbon Earthquake who is reported to have written that "... if this tragedy happened, it is not the fault of mother nature. It was not nature who gathered together twenty thousand buildings in this place." This must be a concern with over half of the world now living in cities and how the provision of interim housing after an earthquake in an urban context will be achieved.

The ability of interim housing to merge into or be the basis of any following housing strategy certainly can be an advantage. It is commonly used in the humanitarian and development sector as transitional or core shelter/housing. However, in developed economies, more reliance is placed on insurance and that those affected will seek their own solutions, and hence emergency

shelters and evacuation centers seem to be the basis for response.

Finally, it seems that shelter in place is the preferred option for those affected by earthquake, and that individual relocation is the least preferred. Yet as noted above with 50 % + of the world's people being urban based suggest that some relocation whether temporary or permanent may need to happen. Consequently, the provision of interim shelter will increasingly become more complex and involved but will still remain as one of the important normalizing steps for communities after an earthquake disaster.

Introduction

The term “land use planning” covers many aspects of planning: spatial, urban design, heritage, transportation, recreation, access to education, health facilities, natural hazards, landscape, biodiversity, air and water quality, affordable housing, cultural values, sustainability, etc., and this is not a complete list of the many aspects and parts to land use planning. A planner may specialize in one of these aspects, e.g., a transportation planner, or be a generalist – knowing a little about many aspects of planning.

There are many definitions of land use planning; however, March and Henry (2007, p. 17) provide a concise discussion on what planning, and more specifically land use planning, is. They state:

Land-use planning ... is focussed upon establishing the best spatial arrangements of land use, development, and management ... To do this, land-use planning is confronted with the task of establishing which of the many potential patterns and organisations of land use are likely to be the most advantageous in the future, in a particular place, and for a particular community.

Therefore, land use planning is an important mechanism for the reduction of risks in the built and natural environments (March and Henry 2007). Although planning cannot avoid all natural hazards, the thoughtfully planned location and design of structures and land uses can reduce the risks, particularly when combined with emergency management systems, i.e., early warning and response systems.

So how does land use planning contribute to recovery following an earthquake? Often touted as the key tool available for sustainable hazard mitigation, land use planning has a key role in determining how a city recovers, its long-term sustainability, and resilience. The following sections will provide an overview of the role of land use planning during recovery following a major earthquake using the 2010–2011 Canterbury earthquake sequence as a case study. This will provide a brief overview of the Canterbury

earthquake sequence and outline the role of governance in planning outcomes, the value of pre-event recovery planning for land use, and the complex post-earthquake realities of planning within the context of the Canterbury earthquakes.

The Canterbury Earthquakes

On September 4, 2010, at 4.36 am, the Canterbury (New Zealand) region experienced a 7.1 magnitude quake. Although there were no casualties, the regional center of Christchurch and the township of Kaiapoi in the Waimakariri District (to the north) suffered extensive land damage in the form of liquefaction, lateral spread (surface rupture and slippage), and rockfall. Six months later, a 6.3 magnitude earthquake occurred almost directly under the city of Christchurch. Though “smaller” in magnitude, the peak ground acceleration of 2.2 (over twice that of gravity) was one of the highest ever recorded and would have “flattened” most world cities (Anderson 2011). This time, 185 people lost their lives and thousands were injured. Almost 80% (Markham 2013) of core inner city buildings were (or will be) demolished; many schools and other major services and facilities closed either permanently or temporarily; there was significant, widespread infrastructural damage; and residents in some hillside and eastern suburbs were left homeless or living in substandard housing. Following this, a 6.3 magnitude quake on June 13, 2011, caused further damage, as did the 50 other quakes with a magnitude of 5 or more. As of March 2013 (Markham 2013):

- With 91 % of the 191,000 homes in greater Christchurch damaged, more than 450,000 residential land, building, and contents damage claims had been made to the Earthquake Commission across 200,000 South Island properties.
- Approximately 7,800 residential homes have been “Red Zoned,” i.e., tagged for demolition or removal with the land under them deemed too expensive to remediate at this time.

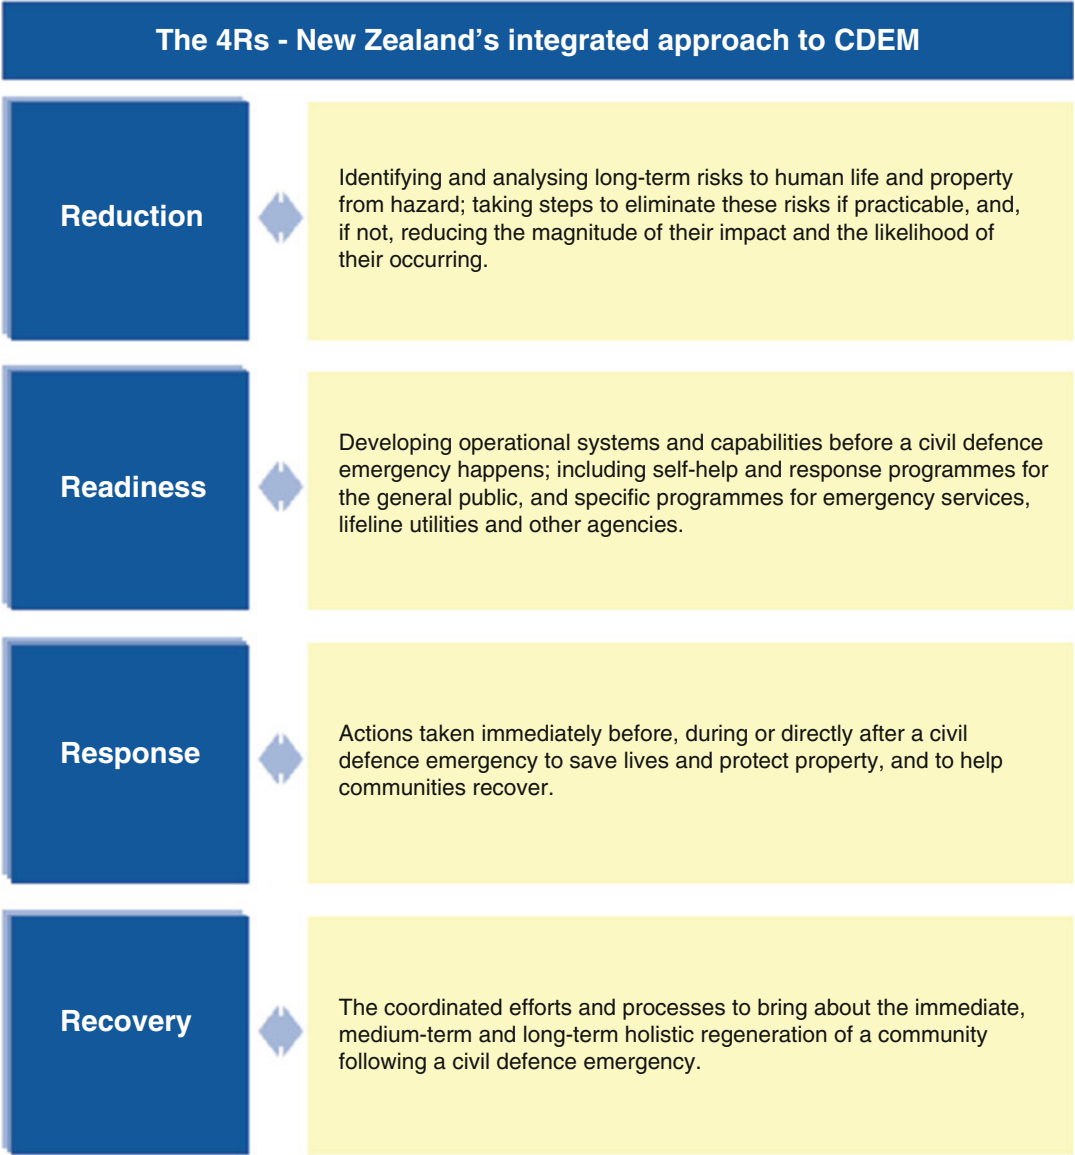

- Over 1,500 central business district (80 % of CBD building stock) and 300 suburban commercial buildings have been, or will be, demolished with over 4,100 businesses (and 30,000 employees) affected by the demolition exclusion zone (initially 390 ha).
- Loss of, or disruption to, 75% of hotel accommodation and key convention, cultural, and recreation facilities, i.e., 1,600 community facilities and more than 250 heritage buildings.
- At least 528 km of the wastewater network, 1,021 km of roads, 22 freshwater wells, and 30 bridges need to be replaced or repaired.
- An estimated rebuild cost of over \$40 billion.

These events have been referred to as the Canterbury Quakes as their effects have cut across district/city council administrative boundaries and have prompted regional migration. The extended sequence has put pressure on local authorities trying to balance “business as usual” with earthquake recovery. New Zealand also has some of the highest levels of insurance in the world; consequently, the region is undergoing extensive “demolish and rebuild” rather than “repair,” the scale of which is causing widespread disruption to residents and debris disposal issues (discussed in section [What is Governance and Why is It Important?](#)). Further, the Red Zone decision has meant the displacement and relocation of almost 8,000 households causing significant land use, infrastructure, housing, and investment changes.

It is within this context that the following sections outline the role of land use planning both pre and post event.

The Role of Land Use Planning in Earthquake Recovery

To ensure consistent outcomes are achieved during recovery, land use planning and emergency management objectives need to be integrated (Saunders et al. 2007). In New Zealand, emergency management is generally

Land Use Planning Following an Earthquake Disaster, Fig. 1 The 4R's of integrated civil defense emergency management in New Zealand (MCDEM 2008, p. 5)

divided into four complementary phases, often referred to as the “4R’s”: reduction (i.e., prevention, mitigation), readiness (i.e., preparation), response, and recovery (see Fig. 1). Land use planning has a key role in the reduction and recovery aspects: reducing risks through avoidance and mitigation of natural hazards, both pre event and during the recovery phase.

How planning and planners respond to recovery is very much dependent on the governance arrangements in place – both pre and post event – as the following discussion outlines.

Role of Governance in Pre- and Post-event Land Use Planning

Disaster management systems around the world have evolved gradually, largely in response to

disastrous events. Typically, the management of disasters, especially large-scale disasters, is a responsibility of governments, as societal institutions and life-sustaining systems are in crisis. During the last few decades, the disaster management practice has been characterized by frameworks and processes based upon a shared system of governance and policy making, with common and overlapping responsibilities apportioned among layers of government (May and Williams 1986). The approach is *ideally* structured to engage from the “bottom-up,” with local governments having primary responsibility for supplying disaster-related resources and regional, subnational, and national agencies providing support as requested. By design, the system requires extensive coordination and cooperation among all levels of government, as well as with the many NGOs involved in disaster management, often in a tiered governance structure (national, state/regional, local) (Johnson and Mamula-Seadon 2014). The related legislation, policies, guidelines, and plans together help to promote a more integrated natural hazards risk management framework and are commonly based upon sustainable development principles (Mamula-Seadon 2009; Saunders and Beban 2012).

This “ideal” approach presumes integrated, decentralized, and deliberative planning and decision-making processes for land use, for development, and for comprehensive risk management, with the central government role defined as setting the direction and providing national policies, while the implementation matters were left to local government (Britton and Clark 2000; Mamula-Seadon 2009). However, recent societal and political changes, such as the emergence of public-private partnerships, outsourcing, and contracting, have meant that functions that may formerly have been carried out by public entities are now frequently dispersed among diverse sets of actors that include not only governmental institutions but also private sector and civil society entities.

What Is Governance and Why Is It Important?

Disaster governance takes a form of collaborative activities through “processes and structures of

public policy decision making and management that engage people constructively across the boundaries of public agencies, levels of government, and/or the public, private and civic spheres in order to carry out a public purpose that could not otherwise be accomplished” (Emerson et al. 2012, p. 2). Implications for land use planning have yet to be fully understood though there is no doubt that the implications are important. Recent literature has started to demonstrate important connections between “procedural” (the process) and “substantial” (the plan) issues that plague peacetime planning, but which are exacerbated by the conditions of uncertainty and urgency that accompany disasters. For example, Kweit and Kweit (2004) compared recovery processes in Grand Forks (North Dakota, USA) and East Grand Forks following severe floods in 1997. After the disaster, East Grand Forks engaged in extensive citizen participation initiatives and subsequently reported on high levels of political stability and citizen satisfaction. In contrast, Grand Forks instigated a more top-down, bureaucratic approach and has since experienced changes to their government structure, a high turnover of elected and appointed officials, and more negative citizens’ evaluations. Similarly, the faltering recovery of New Orleans post Katrina has been attributed, at least in part, to recovery planning processes that failed to engage local communities.

There is a lack of research detailing communities’ planning efforts and aspirations, or their engagement with formal state representatives *post disaster*; however, a great deal of work has been conducted on orthodox “peacetime” models based on, for example, the International Association of Public Participation 2’s spectrum (2014, see Fig. 2). This has a continuum of engagement/participatory practices that range from “token” or “passive” *informing* to consulting, involving, and collaborating, to “meaningful” or “active” *empowering* forms of participation where the agency agrees to implement the community’s decisions. Though these provide useful guidelines, the post-disaster context does add a layer of complexity to these typologies, largely because normal state processes of engagement

Land Use Planning Following an Earthquake Disaster, Fig. 2 IAP2's public participation spectrum (IAP2) (c) International Association for Public Participation www.iap2.org

may be suspended (formally under a state of national emergency or informally due to dysfunction).

Large-scale disasters deplete capital stock and services to a degree where complex rebuilding and societal activities (involving changes to governance) must happen in a compressed period of time. Governments often struggle with these and other time-compressed demands of post-disaster recovery, and as a result, preexisting governance structures – including those around the type and extent of public involvement – are modified or new structures are introduced to help provide more capacity, information, money, and other resources (Johnson and Olshansky 2013).

While these observations have been made, as yet, there has been little detailed study as to how governance structures and processes are often modified post disaster, the conditions by which

governance transformations and new or modified institutions for managing recovery are likely to occur, or what the new structures are able to achieve compared to preexisting structures (Johnson and Mamula-Seadon 2014). Unlike top-down or bottom-up approaches to disaster management, the need for flexibility calls on governments and communities to adapt to, and negotiate, different roles, responsibilities, and opportunities seeking innovative strategies for state-civil society engagement. These offer dramatically improved approaches to building better relations, stimulating more effective activities, and sustaining a flexible and adaptable organizational response (Multi-national Resilience Policy Group 2013).

It is also important to note the disaster recovery planning is embedded in more general governance structures, playing out within ideological,

socioeconomic, cultural, and environmental contexts. Examination of the Canterbury response and recovery process shows how post-disaster “time compression” can spotlight the strengths and weaknesses of disaster management processes and governance frameworks, including land use planning. For governance in general, the Canterbury transformations could be viewed as a rapid governance adaptation embedded within an overall trend in governance reforms underway in New Zealand (Johnson and Mamula-Seadon 2014). Before the earthquakes, the government had already instigated reforms to several key government policy frameworks and accompanying legislation, particularly the Resource Management Act 1991 and Local Government Act 2002, which represent two significant pieces of legislation that govern land use planning in New Zealand.

Ideally governance arrangements should allow for pre-event land use recovery planning to be undertaken. This type of planning requires political commitment and resources; however, the process can prove invaluable post event, as discussed in the following section.

Pre-event Planning for Post-disaster Recovery

While land use planners have a critical role to play in the disaster recovery process, they are often overlooked when preplanning for disaster recovery (Smith 2011). How land use planning proceeds following an earthquake is dependent on what level of pre-event planning has been undertaken before the disaster occurs. The recovery phase can be both prolonged and political; while the response phase might demand rapid technical assessments of the structural safety of a building, the recovery phase associated with that same building may involve interwoven and subjective issues of security, weather-tightness, aesthetics, or broader contextual factors based on infrastructure provision, out-migration of residents, traffic, and access to services and facilities, including schools. Consequently, it may take years, or even decades, for something like “recovery” to occur.

Once a disaster occurs, land use planning efforts for recovery should not be something new – ideally, some planning should begin prior to an event occurring. Planning for land use recovery before an event occurs is different from emergency preparedness and response planning. However, those involved in preparedness and response planning need to be aware of any pre-event recovery planning, and vice versa, to ensure consistency in decision making (Johnson and Olshansky 2013). Where post-disaster recovery is undertaken in an environment that can be detrimental to successful outcomes (e.g., the meaningful involvement of key stakeholders, including communities), pre-event recovery planning allows key stakeholders to invest time and resources to support and encourage cooperative behavior (Smith 2011). Planning for post-disaster recovery and reconstruction requires a collaborative approach to undertake hazard identification, risk assessment, public education, consensus and partnership building, visioning, and the identification of activities that reduce risks (Johnson and Olshansky 2013). A poorly planned or inefficient response to a disaster can impose additional social, economic, and environmental burdens on a community already impacted by the disaster (Johnston et al. 2009).

An example of a framework for pre-event planning is provided in Fig. 3, from New Zealand. This framework has been based on the Standards Australia/New Zealand 31000:2009 Risk Management standard.

There are many opportunities for pre-event planning prior to an event. Questions that can be addressed include:

- Are current land use activities appropriate for their locations? What land is available for relocating particular land use activities?
- What are the social, cultural, economic, and other implications of the land use?
- What aspects of “place” do the community highly value, e.g., historic and cultural character?
- Are there any restrictions (e.g., other natural hazards, sites of cultural significance, building requirements) on the land?

Land Use Planning Following an Earthquake Disaster, Fig. 3 A framework for pre-event planning for post-disaster recovery from New Zealand (Becker et al. 2011, p. 538)

- Do current land use planning policies adequately address the potential for relocating land uses?
- Can the regulatory planning process for (re) development applications be streamlined?
- Where will debris from damaged/demolished buildings, landslides, liquefaction, etc., be disposed of? Consideration needs to be given to:
 - Contaminated material, green material, wood versus concrete, etc.
 - Overflow sites, or prearranging for debris to be transported to another location outside of disaster area
 - The location of staging and sorting sites
- Who are the key stakeholders and community members that need to be involved in preplanning and do they have a recognized role in, for example, civil defense and emergency management programs?
- How healthy are democratic and participatory processes and to what extent is decision-making distributed among different stakeholders?
- What are the short- and long-term planning requirements?
- Can any land use activities be relocated before an event occurs in order to reduce the risk?

There is a significant amount of international research and reporting on the value of pre-event planning for a range of natural hazards, including earthquake. It has also been recognized that preplanning for disaster recovery is important. An example of preplanning for debris disposal following an earthquake is that from New Zealand, where Johnston et al. (2009) have outlined 10 key steps that can be planned by both emergency managers and land use planners, ahead of time. These steps, with those key positions involved in each step, are shown in Table 1.

As shown in the example in Table 1, preplanning for a disaster requires many different parties to be involved in the development of the plan: in this case, emergency managers, planners, communication, and enforcement officers. Undertaking a multidisciplinary approach to pre-event planning, it results in a more comprehensive and robust planning process and outcome.

Pre-event planning can be valuable in building relationships between all of the involved parties, to produce a shared vision and responsibilities for completing pre-event planning tasks, rather than producing the actual plan. As shown in Table 1, building the relationships between the emergency managers, planners, and communication team pre event will mean valuable time is not required to develop these relationships post event. While pre-event planning for recovery should be undertaken before a hazard event occurs, planning can also occur after the event, either before or even while major reconstruction begins. Examples of this type of planning following earthquakes in China, Alaska, and Japan are outlined in Becker et al (2011).

Best practice around both pre-event and post-disaster land use planning shares some similarities, particularly in terms of emphasizing participatory processes. However, much of the theory around disaster-recovery land use planning either belies or underestimates the complexities involved. Recovery planning is unlike “peacetime” planning in that the landscape – geographical, social, economic, political, and conceptual – is likely to be changing rapidly even as the plans are developing. If a disaster is defined as an event which exceeds the ability of a system to cope with the disturbance, causing a loss of functionality, then “chaos,” “confusion,” and “disorder” are trademarks of the response phase. It is this dysfunction that arguably separates disaster from mere misfortune.

In restoring order – or functionality – and transitioning to the recovery phase, it can be helpful to draw upon pre-event comprehensive land use plans and strategies. This ensures that key principles and concerns embedded in “peacetime” (i.e., business as usual) documents continue to guide recovery planning, even if those plans and strategies need extensive modification.

If pre-event plans and strategies do require significant changes, recovery planners will be faced with some key challenges. The obvious need to act with urgency must be balanced against deliberative, inclusive, and participatory processes that are often seen as costly in terms of

Land Use Planning Following an Earthquake Disaster, Table 1 Ten steps for preplanning for debris disposal (Adapted from Johnston et al. 2009)

Key step	Positions involved
1. Develop debris disposal plans at a regional and local level, or make appropriate provisions in existing solid waste management plans. Plans should include a detailed strategy for debris collection, temporary storage and staging areas, recycling, disposal, hazardous waste identification and handling, administration, and communication with the public	Emergency managers
	Planners (i.e., making provisions in existing plans)
	Communication team
2. Identify potential locations or sites for the temporary and/or permanent disposal of debris. Outline a process for final site selection/confirmation in response to post-event requirements in both regional and local plans	Planners
	Emergency managers
3. Prepare a communication strategy ahead of time. You will need to tell your community when, where, and how normal rubbish collection will resume and give special instructions for reporting and sorting disaster debris	Communication team
4. Prepare for increased demands on council staff in terms of public information, operation, and enforcement of debris management systems. This may require additional staff resources to manage the increased workload	Communication team
	Enforcement officers
	Planners
	Emergency managers
5. Make arrangements for additional equipment and supplies to deal with disposal ahead of time. Identify the types of equipment and supplies that staff and contractors will need to carry out operations	Emergency managers
6. Develop mutual aid agreements with neighboring councils (and/or CDEM groups) for plant, equipment, and expertise	Emergency managers
7. Establish pre-event debris management contracts with private contractors	Emergency managers
8. Establish possible organizational structures, roles and responsibilities, and authority between various stakeholders, regulatory authorities, and decision-makers including Ministry for the Environment, Department of Labour, Ministry of Health, and within local authorities	Emergency managers
	Planners
9. Determine financing strategies at local, regional, and national level for differing sizes and types of disaster events	Emergency managers
10. Assess and develop an approach to the potential impact of disaster debris management on normal environmental processes and standards. For example, undertake a Strategic Environmental Assessment identifying practical strategies to minimize environmental and social impacts	Planners

time and other resources. An example concerns the demolition of damaged, and therefore hazardous, buildings versus the preservation of valued and meaningful heritage sites. “Participation” speaks to the notion that engineers, while experts in determining structural safety, may not be best placed to identify a community’s iconic buildings or to assess a building’s importance. There is now enormous debate about the extent to which seemingly apolitical structural or geotechnical matters impact on communities and how both urgent safety concerns and high-level strategic documents can be addressed collaboratively given the degree of trauma experienced by the affected population, the extreme need for timeliness, and, often, a lack of information and other resources.

In summary, pre-event planning for post-disaster recovery can be undertaken before an event occurs, or post-event before reconstruction begins. Pre-event planning should address both short- and long-term needs and involve key stakeholders, including community members. It should be adaptable to post-event realities – the importance of the preplanning is in relationship building and the active participation of key stakeholders.

The Reality of Planning Post-earthquake: The Canterbury Experience

Following the February 2011 earthquake, it was seen as necessary to create an administrative

body to oversee recovery in the post-quake Canterbury region. There were four key reasons for this decision:

1. The earthquake sequence was prolonged with new fault lines identified and significant aftershocks still occurring 2 years after the first event
2. The effects of the sequence were geographically widespread, cutting across four administrative boundaries: the Canterbury Regional Council (ECan), the Christchurch City Council (CCC), the Waimakariri District Council (WMK), and, to a lesser extent, Selwyn District Council (SDC).
3. With a rebuild cost of over \$40 billion, an external coordinating body was seen as necessary to manage the “the political and fiscal risks involved” (Brookie 2012, p. 28).
4. There were concerns that the Christchurch City Council was not able to cope adequately with the scale of the disaster. Councillors were publicly describing the council as “dysfunctional” and “lacking leadership,” and a divide between some of the elected representatives, the Mayor, and the bureaucracy was becoming apparent (Sachdeva 2011).

Consequently, in April 2011 the Canterbury Earthquake Recovery Authority (CERA) was created by an Act of Parliament. Essentially a government department, CERA is responsible to the Minister for Earthquake Recovery, Hon. Gerry Brownlee. CERA is a controversial entity because, through the Canterbury Earthquake Recovery (CER) Act of 2011, the Minister has extraordinary powers to expedite rapid decision-making. While this suits those who want to “get on with it,” others are concerned about the suspension of citizens’ rights and the lack of a layer of governance between CERA and the central government National Party. The CER Act (2011) gives the Minister the ability to suspend, amend, cancel, (or) delay ECan, CCC, or WMK plans or policies, and further, these local government recovery plans must be consistent with CERA’s recovery strategy and signed off by the Minister (Brookie 2012). Among other rights,

CERA’s chief executive has the authority to do the following:

- Require councils to act as directed and or to provide information on request
- Amend or revoke Resource Management Act documents and city plans (i.e., peacetime land use legislation)
- Close or otherwise restrict access to roads and other geographical areas
- Demolish buildings, or otherwise enter and deal with people’s land and property (with notice, in the case of Marae and dwelling houses)
- Require compliance of any person with a direction made under the Act

The CER Act thus forms a controversial legislative and political space where the ends justify whatever means – within which more detailed plans and strategies have been formed. We turn now to a more detailed description of five of these including:

1. The Greater Christchurch Recovery Strategy (GCRS) which is a high-level document providing *strategic direction and principles*
2. The pre-quake Greater Christchurch Urban Development Strategy (UDS) and the post-quake Land Use Recovery Plan (LURP) which has a *regional* focus
3. The Christchurch City Plan covering *metropolitan* Christchurch;
4. The Christchurch Central Recovery Plan (CCRP) which covers the Christchurch CBD;
5. The Waimakariri District Council’s Integrated and Community-based Recovery Framework which guided the infrastructure rebuild program in Kaiapoi

The Greater Christchurch Recovery Strategy (GCRS)

The GCRS was approved by the Canterbury Earthquake (Recovery Strategy Approval) Order 2012 made by the Governor-General. The strategy (Canterbury Earthquake Recovery Authority 2012):

IMMEDIATE	Repair, patch and plan • Provide basic human needs and support services. • Address health and safety issues. • Make safe or demolish unsafe and damaged buildings and structures. • Investigate, scope and initiate recovery programmes and initiatives. • Plan for land use and settlement patterns so land can be made available for displaced residents. • Conduct ongoing programme of investigation and research to understand the geotechnical issues and seismic conditions. Use this information to guide recovery activities and decisions on land suitability for rebuilding.
SHORT TERM	Begin to rebuild, replace and reconstruct • Engage both established and new communities and inform them about rebuilding and future planning. • Establish new social and health support and service delivery models. • Continue demolition of damaged buildings. • Continue repair and rebuild. • Deliver early projects to instil confidence. • Planning and supporting community resilience. • Begin replacement activity. • Begin restoration and adaptive reuse of heritage features. • Continue, monitor and review recovery.
MEDIUM TO LONGER TERM	Construct, restore and improve • Continue to build resilient communities. • Continue reconstruction. • Major construction projects are underway. • Complete restoration and adaptive reuse of heritage features. • Phase out recovery organisations. • Economy is growing and businesses are sustainable. • Labour market is active and attracting employees.

Land Use Planning Following an Earthquake Disaster, Fig. 4 Typical phases of recovery (Canterbury Earthquake Recovery Authority 2012, p. 14)

- Is a high-level document which defines what “recovery” means for greater Christchurch
- Establishes principles to guide how CERA and other agencies will work together towards recovery
- Describes in broad terms the pace and phases of recovery
- Identifies work programs and which organizations will lead specific projects
- Identifies priorities for recovery efforts
- Sets up governance structures to oversee and coordinate the work programs and links them to wider initiatives
- Commits to measuring and reporting on progress towards recovery

In particular, the plan sets out a framework and provides delivery mechanisms necessary to rebuild existing communities, develop new communities, meet the land use needs of commercial and industrial businesses, rebuild and develop the infrastructure needed to support these activities,

and take account of natural hazards and environmental constraints that may affect rebuilding and recovery.

The strategy identifies six components of recovery – cultural, social, built, natural (including geotechnical considerations), and economic. These components link together with the sixth component – community – at the center. Each requires leadership and integration.

The “recovery” process is then divided into three phases (see Fig. 4) – immediate, short-term, and long-term – with each phase assigned milestones and timelines. Immediate actions, like “repairing, patching, and planning,” for example, would ideally have been completed within a year of the first earthquake. Long-term “constructing, restoring, and improving,” on the other hand, may take until 2020 or beyond.

As an example of a recovery strategy, this document does give a good overview of six components that contribute to recovery (i.e., cultural, social, built, natural, economic, and community),

and these components should be considered by others in post-disaster recovery planning. It also provides a good indication of the sorts of recovery milestones associated with different stages of recovery that may usefully serve as a guide for other recovery agencies. On the other hand, implementation is key, and one of the main challenges has been to build both the capability and capacity necessary to deliver on the strategy. Much of the strategy's implementation has been overseen by CERA, but implemented by other local authorities (see Fig. 5) using a blend of both new and existing plans and processes.

The Pre-quake Urban Development Strategy and the Land Use Recovery Plan

In a pre-quake process initiated in 2004 by the Canterbury Regional Council (ECan), the Greater Christchurch Urban Development Strategy (UDS) (Greater Christchurch 2013) was the result of 3 years of collaboration between stakeholders and communities. Based on over 3,250 submissions, the UDS sought to provide a framework for future growth management taking into account risk assessments, transportation, housing demand, and so on. Four options were presented that essentially represented unfettered sprawl at one end, to extreme containment and intensification around core suburban centers and townships in the districts at the other. Discussion around these four options resulted in a vision, guiding principles, strategic directions, and a framework for implementation that was given statutory weight in chapter 12 "Development of Greater Christchurch" of ECan's Regional Policy Statement. This, in turn, guided land use patterns – including areas that could be zoned for residential, commercial, and retail activities – in city- and district-level plans developed by the Christchurch City (CCC), Waimakariri District (WMK), and Selwyn District (SDC) Councils.

The UDS had already signaled areas in the region suitable for future growth when the earthquakes and subsequent Red Zoning decision displaced almost 8,000 households. The comprehensive planning behind the UDS allowed for a fairly rapid appraisal of land that could be

made available to accommodate the demand for new housing. However, the UDS was designed to be implemented over a period of 30 years and considered inadequate for the post-quake context. Consequently, in November 2012, the Minister for Canterbury Earthquake Recovery directed ECan (at their request) to prepare a Draft Land Use Recovery Plan (LURP) through a collaborative multiagency approach involving all of the earthquake recovery strategic partners (including the three local councils, Ngāi Tahu, and the New Zealand Transport Agency), with input from key stakeholders and the wider community.

Some of the key issues included tensions between market-led development and regulation, leadership, certainty, council processes, brown-field development, urban design, housing affordability, infrastructure, public transport, and suburban centers (AERU, 2012). Further, although the LURP had been through several consultative rounds, as the agency responsible for the city plan that will give effect to the LURP, the CCC was particularly concerned that residents had not been sufficiently informed about, for example, the new "design-led" Comprehensive Development Mechanisms (CDMs). These would see high-density housing (defined within the Canterbury cultural context as between 30 and 65 households per hectare) throughout the city. Given that even medium-density housing has a controversial history in Christchurch, the CCC argued for CDMs to be limited to Living 2 and 3 Zones (with minimum site sizes of 330 m² and 300 m², respectively). As so much of the city's public (social) housing stock has been damaged or demolished, a new Community Housing Development Mechanism (CHDM) has also been introduced to facilitate the urgent rebuilding of social housing stock in the city. These are likely to be located in areas that already accommodate such housing. This, too, is likely to be controversial, though criticism may be mitigated somewhat by the review of both mechanisms that is to take place after 5 years of implementation. Nonetheless, tension between the CCC and CERA over CDMs and CHDMs has climbed to very high levels.

Land Use Planning Following an Earthquake Disaster, Fig. 5 The relationship between the recovery strategy and other strategies, policies, and plans for greater Christchurch (Canterbury Earthquake Recovery Authority 2012, p. 22)

The LURP also identifies areas deemed suitable for greenfield development, and with the Minister's approval, statutory effect will be achieved through the insertion of chapter 6 "Recovery and Rebuilding of Greater Christchurch" into the Canterbury Regional Policy Statement. Chapter 6 will then inform district and city plans that more specifically determine the location, type, and mix of business and residential activities within specific geographical areas based on hazard identification, transportation routes, and migration patterns. Through this blend of regional, district, and city plans, the LURP is a significant document that has adopted much of the pre-quake UDS vision; however, it has been described as a "developer-friendly" document that gives the market considerable scope. It has also been criticized for promoting – through peri-urban greenfield and suburban mall development – a further hollowing out of the inner city, the rebuild of which falls under the Central City Recovery Plan (discussed further in section [The \(Christchurch\) Central City Recovery Plan](#)).

The Christchurch City Plan

City and district plans are a pre-quake requirement of all territorial local authorities in New Zealand under the Resource Management Act (1991). These local council plans provide a framework for land use and subdivision in a manner that is consistent with the Regional Council's Plans and Policy Statements (e.g., the UDS/LURP) and are reviewed every 10 years. Christchurch's City Plan was due for review when the quake sequence began and was subsequently delayed until 2013.

Given the extent of the changes that will need to be made to the plan, the council has decided to undertake the review in two stages with the first notification due in 2014 and set to address overall strategic direction; residential, commercial, and industrial land use; subdivisions (e.g., minimum site size); natural hazards; transport; and contaminated land. The second round (in 2015) will notify issues around heritage and the natural environment, the coast, public open space, and so on. Submissions can

be made as the review takes place or once the draft is notified.

While the council has signaled the process may take 3 years, some of the proposed changes – such as the CDMs, CHDMs, and greenfield development mentioned above – are likely to be controversial as are other issues around, for example, maximum height and parking restrictions, "permitted" activities such as light retail, and so on.

The (Christchurch) Central City Recovery Plan

Following the February 22, 2011, earthquake – which led to the demolition of almost 80 % of building stock in the CBD core (Markham 2013) – the Christchurch City Council began the task of developing a recovery plan for the central city. In May of 2011, the CCC initiated the 6-week *Share an Idea* campaign which, according to the CCC website (Christchurch City Council 2013a), allowed "the public to tell us their ideas about how the Central City should be redeveloped to be a great place again. ..." Combining a weekend of on-site opportunities and an online crowd-sourcing tool, the campaign generated more than 106,000 ideas from over 60,000 participants. These ideas were analyzed so as to inform the draft Central City Plan and guide inner city development for the next 10–20 years.

Share an Idea was followed by another participatory tool – the *48 h Design Challenge* – run by the CCC at Lincoln University. This provided an opportunity for the council to work with the design and architecture industry and practically test the draft Central City Plan over seven preselected sites. A total of 15 teams comprising engineers, planners, urban designers, architects and landscape architects, and students took part in the *Challenge*.

Following these exercises and other, smaller workshops, the Draft CCP was delivered to the Mayor to sign off in August of 2011 before being sent to the Minister for Earthquake Recovery for his approval. Submissions were invited and 79 comments were received. As outlined on the council's website (Christchurch City Council 2013b), the Minister's view was that "taking into account its impact, effect and funding

implications, [the Plan] could not be approved without amendment...given insufficient information...on how the Recovery Plan would be implemented and changes to the District Plan that [are] unnecessarily complex.”

Consequently, the Minister established a special unit within CERA, the Christchurch Central Development Unit (CCDU) which was to work with a “professional consortium” to deliver, within 100 days, the Central City Plan and take a lead role in its implementation alongside the CCC, Te Rūnanga o Ngāi Tahu, and other key stakeholders. The CCRP is based on a master-planned blueprint for the CBD providing street layout, the location of “anchor” projects (including a convention centre and sports facility), and various precincts. These they hope will stimulate further investment and development (though this has been hamstrung by the need to meet new building standards, current requirements for parking spaces, and so on, often with insurance pay outs that only covered the replacement value of old buildings).

Given the responsibility for the 100 Day Plan was taken from the CCC and given to a nonelected, newly created entity – the CCDU – amidst controversy around compulsory land acquisition to enable the anchor projects to go ahead, the level of public involvement may have been limited. Though the plan’s executive summary states that “The city centre [will be]...a reflection of where we have come from, and a vision of what we want to become” (Central City Development Unit 2012, p. 4), it has been suggested that, in practice, the process has been “top-down, centralised, and highly bureaucratic” (in Brookie 2012, p. 29). Drawing on the IAP2’s spectrum of participation (see Fig. 2 above), it could be argued that much of the “involvement” behind the plan’s development is limited to “informative and consultative” rather than “collaborative and empowered.”

Underlying the attempt to design a Central City Plan within 100 days is a sense that urgency both demands and justifies the suspension of peacetime processes around public engagement, transparency, and accountability. It is claimed, for example, that “The experience of other cities

after a natural disaster shows that substantial redevelopment must start within 3 years if recovery is to be successful. One year has passed. Speed is of the essence...” (Central City Development Unit 2012, p. 4). Consequently, the policies and procedures for land acquisition have been both praised as providing swifter certainty for homeowners and businesses to relocate and recover and criticized as having evolved over time with often reactive and unclear reasoning. Similarly, while the CCDU has been credited with accelerating the design and implementation of the CBD rebuild, concerns have also been raised about the acceptance of development applications without the establishment of clear criteria for screening and selecting among competing applications (McDonald 2013).

This raises questions about whether it is possible to effectively and adequately reconcile the conflict between the perceived need for urgent decision-making and action, on one hand, and robust process on the other. In exploring possible answers to this question, we turn now to an example of recovery best practice: The Waimakariri District Council’s Integrated and Community-based Recovery Framework.

The Waimakariri District Council’s Integrated and Community-Based Recovery Framework and the Kaiapoi Infrastructure Rebuild

The Waimakariri District is adjacent to the city of Christchurch with a population of about 50,000 people. It has traditionally been described as agricultural with large farms, lifestyle blocks, and smallholdings devoted to horticulture; however, a few settlements have grown rapidly and now form a commuter corridor of townships, with many residents traveling to work in Christchurch each day.

After the September 2010 earthquake, parts of the Kaiapoi township suffered extensive land damage from liquefaction and lateral spread, and over 1,000 households and the town center were severely affected. Besides serious damage to a quarter of its housing stock, Kaiapoi also lost its library, aquatic center, community halls, churches, the movie theater, bars, and cafes. Over 25% of businesses were immediately

affected and there have been significant relocations and a number of permanent closures. Much of the infrastructure was affected leaving 5,000 people without water and sewer. The damage, *proportionally*, was similar to that experienced in Christchurch.

Despite it being a Saturday, many WMK staff members came to work either to assume their post in the Emergency Operations Centre or to volunteer to help in Kaiapoi. By late afternoon, council staff members were distributing information on foot to affected residents. Other departments from “business as usual” started taking place, some of which meant literally and figuratively “stepping across a boundary.” As reported by a WMK senior manager (see Vallance 2013 for the full document):

Traditionally councils do not step across the home-owner’s boundary and any infrastructure issues between the house and the front boundary is the home-owner’s problem. But [due to demand] post-earthquake it would have been impossible to just call a plumber to get the issue fixed. So we [Waimakariri District Council] made a decision fairly early on to liaise with [and secure funding from] the Earthquake Commission and coordinate repairs *across the boundary* because there’s no point us fixing our side of the sewer and people still not being able to use [the toilet] because the pipe between the house and the boundary is broken (*italics added*).

Other councils did not take on this coordination role as quickly and, as a result, some of their residents suffered for months with poor sanitation.

Other initiatives included three new Recovery Manager positions. The Social Recovery Manager (previously the council’s peacetime Community Team leader) was moved from the Rangiora offices to Kaiapoi to “colocate” with engineering and utilities council staff and contractors at the newly established Recovery Assistance Centre. She began acting as a liaison between engineers and contractors and Kaiapoi residents, local NGOs, and community groups. This communication between, and early involvement of, locals significantly shaped subsequent decisions to undertake the project management of what was thought to be (at the time) a neighborhood infrastructure rebuild program.

The neighborhood infrastructure rebuild program – coordinated by the newly appointed Infrastructure Recovery Manager – served about 1,200 households, broken down into smaller clusters for rebuild in different stages. It was argued that 1,200 was about the “right amount” and that if the project had been much larger, a different approach may have been required.

Importantly, the communication with residents around this staged rebuild was both deliberative and inclusive and began with numerous public meetings. These included “Q and A sessions” where, often, residents were seated according to the street in which they lived so they could get to know each other (for support) and triangulate information at a very local level. Elected councillors and senior managers from the council (often including the CEO and/or the Mayor) along with representatives from the insurance companies and geotechnical experts were also present. These meetings were well documented and the notes turned into a booklet that was then put on the council’s New Foundations website that had been established solely to disseminate earthquake-related information.

The council then published an order of works with timeframes (see Fig. 6). This was critical as it allowed affected residents to plan ahead for their temporary relocation. However, it is noted that events overtook the feasibility of that particular plan, so it was not implemented. The council also helped coordinate the provision of temporary housing located on council reserve land to accommodate residents displaced by the rebuild. Residents who were “last in the queue” of the staged rebuild were supported by the volunteer-led pastoral care team who liaised weekly with the Social Recovery Manager and who now shared a port-a-com with the Infrastructure Recovery Manager at “the Hub” in Kaiapoi.

The Hub was designed to be a “one-stop recovery shop” and was located in the council-owned community hall in Kaiapoi. It also housed the council’s pre-quake Kaiapoi Service Centre staff, some of the council’s Building Unit and Community Team usually located in Rangiora, Work and Income New Zealand, the Inland Revenue Department, local NGOs providing business

Land Use Planning Following an Earthquake Disaster, Fig. 6 The Waimakariri District Council's Schedule of Works for Kaiapoi (www.newfoundations.org.nz)

and whānau support, psychosocial and pastoral care teams, a tenancy service, Fletchers (one of the approved building repair companies), and the 15 Waimakariri Earthquake Support Service (WESS) coordinators who, in the first 2 years, assisted between 400 and 600 cases with accommodation, help with earthquake claims, legal aid, and counseling for earthquake stress. A dedicated earthquake communications manager was also appointed and colocated in the Hub. This colocation, right in the heart of Kaiapoi, enabled engineering expertise to reach residents and community intelligence to inform infrastructural recovery. The communication between the Social Recovery and Infrastructure Recovery Managers helped the engineering and utilities teams to appreciate the positive and negative impacts of their work and for residents to better understand what engineers and other experts were doing, and why.

While it is difficult to make direct comparisons between Christchurch and Waimakariri given the different contexts, types of plans, and extent of damage, satisfaction with the Waimakariri District Council's recovery framework for the first 3 years is relatively high. Indeed, as reported in Vallance (2012), a Residents' Association representative said:

There is a very good understanding on behalf of the majority of the community that the Waimakariri District Council understood the community's needs, that recovery was shared with the community so the community were engaged in different ways. If you want an example of recovery best practice, you've got it right there.

Wider support for their framework may also be reflected in the local government elections of 2013 where 9 of 10 councillors were reelected, with the Mayor unchallenged. In Christchurch, the results were quite different with only 4 of 13 representatives reelected (with the Mayor

and two others resigning). There are, therefore, some interesting parallels between these results and those documented by Kweit and Kweit (2004), reported above.

Summary

This chapter has outlined the role of land use planning during the complex and demanding recovery phase, with examples from the Canterbury region in New Zealand. Land use planning has a key role to play in the recovery phase; however, to strengthen this role, planning needs to be undertaken before an event occurs.

While any pre-event plan will need to be adapted or even rewritten post an event, the value is in the process of bringing key stakeholders together to discuss issues, agree on common goals, and form relationships that will be key during a recovery phase. Pre-event recovery planning can be useful as a means of rapidly appraising available land, as the Urban Development Strategy showed; however, such plans need to be flexible and adaptable. The Greater Christchurch Recovery Strategy highlights the value of developing an overall guiding strategy, but building capability and capacity to deliver on the strategy can be difficult and lead to high levels of tension between different recovery agencies. To support pre-event recovery planning for land use, governance arrangements need to be in place that enable pre-event planning and support the planning process post event when time compression factors influence the “business as usual” community consultation and engagement process.

As the five case studies from Canterbury have shown, the reality of recovery is complex, involving political intervention from a national level into local decision-making and governance arrangements. This in turn has directed how recovery plans have been produced, the involvement of the community in their development, and their outcomes. The Canterbury earthquake case study highlights some important lessons for those involved in recovery planning and the relationship between process and reality.

Introduction

With an average occurrence rate of 20,000 events worldwide every year, earthquakes have produced innumerable fatalities and economic loss (Fig. 1). For example, the recent Haiti earthquake (2010) was responsible for at least 300,000 injuries, 316,000 deaths, and 300,000 destroyed houses. There is a high demand for rapid and real-time health evaluation of post-earthquake structures as it is critical to distinguish which structures are inhabitable and serviceable and which are damaged and unavailable anymore. However, current evaluation methods are labor intensive, time consuming, and not cost effective.

Structural health monitoring (SHM) refers to the process of determining and tracking structural integrity and assessing the nature of damage in a structure (Chang et al. 2003). The process of SHM usually consists of four stages: (1) damage definition, (2) damage identification, (3) damage localization, and (4) damage quantification. SHM has been studied since the 1970s and primarily studied within the context of contact-type sensors. These contact sensors include accelerometers, strain gauges, acoustic emission transducers, and fiber-optic sensors, to name a few. However, it is challenging to utilize these sensors for

Laser-Based Structural Health Monitoring,

Fig. 1 Number of worldwide earthquakes during 2000–2011 (Source: United States Geological Survey)

post-earthquake monitoring as most of the installed sensors would be destroyed during the earthquake, and there would be no enough power supplies to operate these sensor systems.

In this entry, noncontact laser sensing is introduced as an alternative means for SHM. Light detection and ranging (LiDAR) and laser Doppler vibrometer (LDV) are two of the most common laser-sensing systems. A LiDAR estimates a distance from the device to a target point by measuring the time of flight (TOF) of the incident laser pulse reflected off from the target point or by measuring the phase shift of the reflected laser beam with respect to the incident continuous wave laser beam (Wehr and Lohr 1999). On the other hand, an LDV estimates the out-of-plane velocity of a vibrating target by relating the velocity to the frequency shift of the reflected laser beam with respect to the incident laser beam (Castellini et al. 2006). Furthermore, these devices can be easily deployed for long-range sensing and large area scanning. Figure 2 shows typical LiDAR and LDV devices. Riegl VZ-6000 LiDAR (Fig. 2a) can measure up to 6 km with an accuracy of 15 mm and a measurement speed of 37,000 points/s. Its measurement speed can be increased up to 222,000 points/s, but the maximum measurement range is shortened to 3.3 km. Polytec PSV-500 LDV (Fig. 2b) can measure up to 50 m/s vibration with a resolution of $2 \mu\text{m/s}/\sqrt{\text{Hz}}$ and a maximum vibration frequency of 2.5 MHz.

This entry is organized as follows: In Section “Working Principles of LiDAR and

LDV,” airborne laser scanning techniques for regional damage assessment are summarized. Section “Airborne Laser Scanning for Regional Monitoring” presents ground-based laser scanning techniques for global and local damage detection, and Section “Ground-Based Laser Scanning Techniques” discusses laser ultrasonics and thermography for local damage detection. Finally, the conclusions and discussions are summarized in Section “Other Laser-Based Techniques for Local Damage Detection.”

Working Principles of LiDAR and LDV

In this entry, the working principles of LiDAR and LDV are discussed in more detail. LiDAR can work in two manners, (1) TOF measurement and (2) phase-shift measurement. The first one is more commonly used for commercial LiDAR, which is rather simple to understand (Fig. 3a). A high-power laser pulse is emitted from the LiDAR, and the laser pulse reflects back from the target object. When the reflected laser pulse is detected by the LiDAR, the distance to the target D is determined as

$$D = \frac{T}{2}c \quad (1)$$

where T and c denote the TOF, which is the time difference between laser pulse emission and reception, and the speed of light (3×10^8 m/s), respectively. As the distance measurement via LiDAR

Laser-Based Structural Health Monitoring, Fig. 2 Representative laser scanning devices: (a) light detection and ranging (LiDAR) and (b) laser Doppler vibrometer (LDV)

depends on the reception of the reflected laser pulse, the sensing ranging of LiDAR is mainly limited by the laser pulse power. Some commercial LDV devices with a very high-power pulse can measure distance up to several kilometers.

Displacement measurement based on phase shift estimates the TOF information from the phase shift of the reflected laser beam (Fig. 3b) with respect to the incident laser beam. It emits an amplitude modulated laser beam and compares it with the reference laser beam. Then the phase difference φ between two laser beams can be expressed as follows:

$$\varphi = 2\pi T f_m \quad (2)$$

where f_m refers to the modulation frequency of the laser beam. By substituting Eq. 2 into Eq. 1, the distance is estimated as

$$D = \frac{T}{2} c = \frac{\varphi}{4\pi f_m} c = \frac{\varphi}{4\pi} \lambda_m \quad (3)$$

where λ_m refers to the wavelength of the amplitude modulation which is typically ranging from

100 to 500 m for common LiDARs. The biggest drawback of the phase-shift-based displacement measurement is that its ranging capability is usually limited to several hundred meters, as $0 \leq D \leq \frac{\lambda_m}{2}$ in Eq. 3. However, its measurement speed can be up to 1 million points/s, which is much faster than the TOF-based measurement technique (usually $\sim 10,000$ points/s).

Figure 4 represents a schematic diagram of a common LDV. Assuming that a target is vibrating with a velocity of v , the frequency of the laser beam reflected from the moving target changes from its initial value of f_0 to the following value based on the Doppler effect:

$$f = \left(1 - \frac{v}{c}\right)^2 f_0 \quad (4)$$

where f denotes the frequency of the reflected laser beam. Note that v becomes negative when the target is vibrating toward the LDV. The intensity of the reflected laser beam can be expressed as

$$I_r = I \cos(2\pi f t) \quad (5)$$

Laser-Based Structural Health Monitoring, Fig. 3 Schematic diagram of LiDAR measurement working principle. Red solid line and blue dotted line denote the paths of the reference and reflected laser beam,

respectively. BS, D, T, and φ refer to a beam splitter, distance to the target, time of flight of the reflected laser pulse, and phase difference between two laser beams, respectively

Laser-Based Structural Health Monitoring, Fig. 4 Schematic diagram of a common LDV. Red solid and blue dotted lines denote the paths of the reference and reflected laser beams, respectively. PBS, BS, AOM, and M refer to a partial beam splitter, a beam splitter, an acousto-optic modulator, and a mirror, respectively

where I and t refer to the maximum intensity of the laser beam and time, respectively. This reflected laser beam interferes with the reference laser beam:

$$I_0 = I \cos(2\pi(f_0 + f_{AOM})t) \quad (6)$$

which originally has a frequency of f_0 but shifted to $f_0 + f_{AOM}$ by an acousto-optic modulator (AOM). f_{AOM} is usually set to 40 MHz for many commercial LDVs. Then the intensity of the interfered laser beam is

$$\begin{aligned} I_i &= I \cos(2\pi(f_0 + f_{AOM})t) + I \cos(2\pi f t) \\ &= \frac{I}{2} \cos(2\pi(f_0 + f_{AOM} + f)t) \\ &\quad + \frac{I}{2} \cos(2\pi(f_0 - f + f_{AOM})t) \end{aligned} \quad (7)$$

By applying a low pass filter to I_i ,

$$I_i^{LPF} = \frac{I}{2} \cos(2\pi(f_0 - f + f_{AOM})t) \quad (8)$$

where $f_0 - f$ can be expressed as

$$\begin{aligned} f_0 - f &= f_0 - \left(1 - \frac{v}{c}\right)^2 f_0 = f_0 \left(1 - \left(1 - \frac{2v}{c} + \frac{v^2}{c^2}\right)\right) \\ &= f_0 \left(\frac{2v}{c} + \frac{v^2}{c^2}\right) \end{aligned} \quad (9)$$

Since v is very small compared to c , we have

$$f_0 - f \simeq f_0 \left(\frac{2v}{c}\right) = \frac{2v}{\lambda_0} \quad (10)$$

$$I_i^{\text{LPF}} = \frac{I}{2} \cos \left(2\pi \left(\frac{2v}{\lambda_0} + f_{\text{AOM}} \right) t \right) \quad (11)$$

where λ_0 is the wavelength of the incident laser beam. Then, by measuring the frequency of the interfered laser beam, the velocity of the target v can be estimated. Note that f_{AOM} is introduced to distinguish positive and negative frequency shift from the interfered laser beam frequency. Because LDV measures velocity from the Doppler frequency shift of the reflected laser beam, the signal-to-noise ratio of LDV heavily depends on the reflectivity of the target surface. Therefore, special surface treatments such as a retroreflective tape are often required for the improved signal-to-noise ratio, but it can be rather challenging to treat surfaces of target structures in the field.

Airborne Laser Scanning for Regional Monitoring

Airborne laser scanning (ALS) techniques utilize a laser device mounted onto aircraft to monitor earthquake-affected areas. Aerial techniques with fast and extensive data acquisition availability, such as aerial and satellite imaging, have been extensively used for large area scanning. The ALS techniques have a big advantage over the 2D imaging techniques because they can gather and reconstruct height/depth information for 3D model construction (Fig. 5). Two ALS schemes are introduced in this section. In the first scheme, ALS is used to detect changes in urban features

and discern which structures are collapsed or damaged. Then, the structural damage type is identified and classified through the second ALS scheme.

Change Detection from Urban Features

Once a 3D model of the region is constructed by ALS scanning, the regional changes can be detected by comparing models before and after any event occurrence. This scheme has been applied for various purposes including forest observation and coastline monitoring. This ALS has also been applied to extracting urban features including land uses and structural identification (Priestnall et al. 2000).

Vu et al. (2004) scanned over Roppongi, Tokyo, Japan in 1999 and 2004. They compared two models and calculated the height difference at each 2D grid. Via the use of statistical analysis and filtering processes, they were able to identify outliers, which have distinctive height changes compared to the average height change of the whole scanned region. These outlier points are considered possible new constructions (height increased) and demolitions (height decreased). This concept can be applied to rapid inspection of earthquake-affected regions, but requires continuous update of the urban ALS models for comparison.

Shen et al. (2010) proposed another monitoring technique to identify demolished buildings by measuring buildings' inclinations from ALS data. They extracted a vertical axis vector of a building from its roof geometry and compared it with the ground normal vector to determine the buildings' inclination. As these two vectors can be gathered from a single ALS image, there is no requirement for previous or baseline model scanned for this technique. They applied this technique to a building affected by the Haiti earthquake and identified its inclination angle.

Classification of Structural Damage

During the rescue operation for earthquake victims, rapid assessment and classification of structural damage types is very critical to set the rescue strategy, allocate recourse, and save as many lives as possible. Schweier and Markus (2006) classified types of building damage after

Laser-Based Structural Health Monitoring,

Fig. 5 (a) Conceptual figure for the airborne laser scanning (ALS) technique and (b) an example of scanned model

earthquakes into 10 categories including inclination, pancake collapse, and heap of debris (Fig. 6). However, it turned out to be vexing and challenging to classify them using 2D imaging data as it does not contain height information. For example, a pancake-collapsed building cannot be easily recognized with 2D imaging techniques as its identical top-view image remains intact.

Rehor (2007) scanned a military training area in Swiss and compared the model with its original CAD blueprint to classify structural damage types of each building. Changes in building features including area size, inclination angle,

volume, and height are identified from the comparison.

The damage classification process is automated by introducing fuzzy logic membership functions for each feature. Fuzzy logic is one of the soft computing techniques, which enables the use of probability for logical analysis. For damage classification, the probabilities of all damage categories associated with each specific feature are computed using Fuzzy logic membership functions. For example, the membership functions of the feature “change of inclination” are shown for “the pancake collapse” and “inclined

 1. Inclined plane	 2. Multi layer collapse	 3. Outspread multi layer collapse	 4 a) Pancake collapse, first floor	 4b) Pancake collapse, intermediate story	 4c) Pancake collapse, upper story
 5. Pancake collapse, all stories	 5a) Pancake collapse, several lower stories	 5b) Pancake collapse, intermediate stories	 5c) Pancake collapse, upper stories	 6. Heap of debris on uncollapsed stories	 7a) Heap of debris
 7b) Heap of debris with planes	 7c) Heap of debris with vertical elements	 8. Overturn collapse, separated elements	 9a) Inclination	 9b) Overturn collapse	 10. Overhanging elements

Laser-Based Structural Health Monitoring, Fig. 6 Building damage types after an earthquake (Rehor 2007)

Laser-Based Structural Health Monitoring, Fig. 7 Fuzzy logic membership function example for pancake collapse and inclined plane (Rehor 2007)

plane” damage categories in Fig. 7. If a building had an inclination angle of 5°, this building would have a 0.9 probability for the pancake collapse and 0.25 for the inclined plane. On the other hand, if the inclination angle of another building were 20°, the probabilities for the pancake collapse and the inclined plane would be 0 and 0.9, respectively. The probabilities for other feature values are estimated in a similar manner, and the damage category with maximum probability is classified as the most probable damage category. As a result, damage types of 13 out of 17 (77 %) buildings are correctly classified. Rehor and Voegtle (2008) improved the classification accuracy to

88 % by integrating multispectral scanner data and aerial images with the above ALS model.

Ground-Based Laser Scanning Techniques

While ALS techniques are able to inspect large areas with a high speed, its damage detectability is rather limited to the detection and classification of large-scale defects. Further investigation of the structures, which are classified as intact with the previous ALS techniques, is often required as there still is a high possibility of internal damage

Laser-Based Structural Health Monitoring,

Fig. 8 (a) Scanning of the Ashdown House in UK using a ground-based laser scanner and (b) the resultant 3D model (© Halcrow Group)

Ground-based Laser Scanning

Scanned 3D Model

in these structures. In particular, this detailed inspection could be critical for post-earthquake re-occupation of buildings as the undetected internal damage may lead to the collapse of the structures and additional casualties. A number of contact-type sensors have been suggested for the detailed inspections, and recently LiDAR and LDV are gaining prominence due to their noncontact nature. In this section, ground-based laser scanning techniques for global and local damage diagnosis are presented (Fig. 8).

Serviceability Monitoring Through Deflection/Deformation Measurement

Serviceability refers to the conditions under which a building is still considered useful.

The serviceability is typically evaluated by measuring a local deflection and deformation, and the structure is considered in a proper serviceable condition when the deflection remains within a certain limit. However, deflection measurement on large-scale structure has always been a daunting task.

This problem can be readily solved with a LiDAR. As previously mentioned, LiDAR can measure 3D displacement of a structure as well as its static and dynamic deformed shapes. One of the biggest problems is that the maximum displacement measurement error of LiDAR is up to 10 mm, which may be insufficient for SHM purposes. Park et al. (2007) overcame this problem by introducing a displacement measurement

model to calibrate the error and reduced the measurement error to less than 1 mm compared to the one measured by contact-type sensors such as LVDT, strain gauge, and fiber-optic sensor.

LiDAR has been applied not only in laboratory settings but also in the field. Watson et al. (2012) scanned a highway bridge for underclearance measurement with traffic and temperature variations. They performed correlation analysis between the measured underclearance, traffic, and temperature variations and concluded that LiDAR can consistently measure the underclearance value without environmental dependence. Liu et al. (2010) carried out a static loading test on a steel girder bridge while measuring its deformation with a LiDAR and reported its behavior under truck loading.

Vibration-Based Damage Detection

Vibration-based damage detection is one of the most widely adopted SHM methods for field applications. This technique attempts to evaluate the global integrity of a structure by relating the change of modal parameters such as natural frequencies, mode shapes, and damping to the physical properties of the structure such as stiffness and mass. Conventionally, these modal parameters are measured by contact-type accelerometers, but they can be substituted with a noncontact laser scanner. Nassif et al. (2005) reported that the bridge girder vibration and displacement measured by an LDV match very well with the ones obtained by geophone sensors and LVDTs attached to the girder.

When it comes to vibration measurements, LDV is a preferred noncontact solution rather than LiDAR because modal analysis requires measurement of vibration signals with a high sampling rate. LDV can achieve a sampling rate up to several MHz, while it is usually limited up to 1 kHz in LiDAR. Siringoringo and Fujino (2009) detected damage in a structural member by performing modal analysis using an LDV. They scanned a bolted joint plate and compared modal parameters measured from different bolt-loosening conditions. Stiffness and damping

changes due to the loosened bolt torques were observed, and damage size was quantified. Khan et al. (2000) detected various cracks with an LDV, including through cracks in thin plates, narrow slots in a solid cantilever beam, and cracks in a reinforced concrete beam by comparing mode shapes and frequency response functions of the specimens before/after introducing damages.

Laser Model-Based Damage Quantification

The scope of the previously overviewed vibration-based damage detection is typically limited to damage identification and localization. For damage quantification, additional steps are warranted. The principle of the damage quantification techniques presented here is quite similar to the aforementioned ALS techniques. One of the quantification algorithms is volumetric change analysis (Olsen et al. 2010). By comparing the original and the posttest 3D models obtained from laser scanning, volumetric changes, or defects of the concrete structure, can be detected. The scanning process in Olsen et al.'s study took about 6 h to scan a concrete structure of 6.706 m³, while a conventional photographic technique required 20 h of manual photo-taking. Liu et al. (2011) suggested two other damage quantification methods, which do not require a baseline laser-scanned model. In these methods, damage is identified by measuring surface flatness and smoothness. When a local defect like spalling appears on a concrete surface, the depth and normal direction of the defect area will deviate from a reference (undamaged) plane. The depth and angle deviation of the damaged concrete surface from the intact surface are computed using the full 3D coordinate information of the target concrete structure obtained by LiDAR. While the depth information is good for detecting the deepest portion of the damage area, the angle variation is more sensitive to the edge of the defect, where a sudden gradient change of the concrete surface is expected (Fig. 9). They inspected a real concrete bridge by integrating both methods and identified mass loss in concrete members (Fig. 10).

Laser-Based Structural Health Monitoring,

Fig. 9 Schematic diagram for surface damage quantification by measuring the depth and angle deviation

Fig. 10 Defect detection for a concrete bridge member using LiDAR scanning, presented by Liu et al. (2011)

Other Laser-Based Techniques for Local Damage Detection

After earthquakes, small defects may not pose an immediate threat to the overall structural integrity or cause a sudden collapse of the structure. However, hidden and untreated defects will continuously grow and eventually compromise the safety of the system. Therefore, there is an increasing demand to further improve damage detectability and identify defects as early as possible. Furthermore, as sensing techniques advances, the detection of small-scale defects, which was not feasible using conventional

techniques, is becoming feasible. Here, two specific state-of-the-art techniques for such micro-scale damage detection, laser ultrasonic imaging and laser thermography, are presented. Although they have been mostly applied for inspection of mechanical systems so far, their brief introduction is included here because of their great potential for SHM of earthquake-affected structures (Fig. 11).

Laser Ultrasonic Imaging

Ultrasonic techniques identify a defect by measuring interaction between ultrasonic waves and the defect. Conventionally ultrasonic waves are

generated and measured using contact-type transducers such as piezoelectric transducers (Kim and Sohn 2007), but nowadays noncontact laser solutions are available. When a high-power pulse laser beam is exerted onto a solid surface, a localized heating and corresponding elastic expansion of the specimen produce ultrasonic waves (Scruby and Drain 1990). The generated ultrasonic waves can be measured using an LDV. With its scanning capability, ultrasonic waves generated from a single point can be measured from multiple points with high spatial resolution in the order of mm. Once the ultrasonic responses are measured from multiple scan points, the wave propagation in a spatial domain and its interaction with a defect can be visualized. An et al. (2012, 2013) apply laser ultrasonic imaging techniques to the detection of a notch in a steel bridge girder and a notch in a metal plate (Fig. 12). In their study, a high-power pulse laser

beam is scanned over the inspection region for ultrasonic wave generation, and the corresponding responses are measured at a single point using an LDV. In theory, the ultrasonic image obtained by scanning the excitation laser beam with a fixed sensing point is identical to the one obtained by scanning the sensing laser beam with a fixed excitation point based on linear reciprocity. In practice, scanning the excitation laser beam is more advantageous as the performance of LDV usually varies with the surface condition and the incident angle of the sensing laser beam.

However, there are several hurdles that need to be overcome for field applications. The laser ultrasonic generation requires the use of a class IV high-power laser over 1 MW, which may harm human eyes. The scanning time for large area inspection with high spatial resolution can be prohibitively long. Currently laser ultrasonic techniques are best suited for inspection of

Laser-Based Structural Health Monitoring, Fig. 13 Crack detection in a steel test specimen using laser thermography, presented by Li et al. (2011)

metallic and composite materials, and the applicability to porous materials including concrete is limited due to rough surface conditions.

Laser Thermography

Infrared (IR) thermography techniques visualize and quantify damage by detecting changes in heat transfer characteristics near the defect. As thermal images can be taken over a large area rather quickly using the IR camera, this technique has been popular for nondestructive testing of mechanical systems. Clark et al. (2003) detected delamination in a concrete slab of a real bridge, by using natural sunlight as a passive heat source and taking thermal images. By detecting regions with abnormal temperature in comparison with the rest of the areas, possible damage locations were recognized. However, the maximum temperature differences remained below 1 °C, making it challenging to distinguish damage regions from the rest.

This leads to the development of active thermography techniques, where a controlled heat source such as a halogen lamp and acoustic transducer is used (Chatterjee et al. 2011). A laser thermography technique is relatively new in the field of active thermography and uses a high-power laser as a heat source. Compared to a

traditional heat source such as a halogen lamp, the biggest advantage of the laser is its highly localized nature of heating spot. This helps to improve the damage detection resolution and defect micro-cracks. Li et al. (2011) visualized a 50 μm wide and 5 mm long fatigue crack in a mild steel test piece (Fig. 13). However, it should be noted that the application of the laser thermography technique is usually limited to the detection of surface damages in thin structures, and it requires history baseline data collected from the intact condition to identify damage, which may show false alarms in the presence of operational and environmental variations.

Summary

Laser-based structural health monitoring is a promising technology for the monitoring of earthquake-affected structures as it does not require any sensor nor power/data cable installation. Light detection and ranging (LiDAR) and laser Doppler vibrometer (LDV) are two of the most widely adopted laser-sensing devices for civil applications due to their noncontact nature and high measurement accuracy. LiDAR estimates the distance to the target by measuring

time-of-flight or phase-shift information of the laser beam reflected off the target, and LDV measures the vibration velocity of the target by relating the frequency shift of the reflected laser beam.

Various laser-based structural health monitoring techniques applicable to earthquake-affected structures have been proposed and briefly discussed in this entry. By means of airborne laser scanning (ALS), earthquake-affected regions may be rapidly monitored for distinguishing damaged structures and further identifying their damage types. Even for intact structures, LiDAR-based displacement/deformation measurement can be used to check the serviceability of civil infrastructure. The damage location and size can be quantified with LDV-based vibration analysis and LiDAR-based 3D structural model. Additional laser techniques with potential application to post-earthquake inspection include laser ultrasonic techniques and laser thermography techniques, which are able to detect small-scale damages.

Still there are several challenges associated with field deployment of these laser devices: (1) the time-of-flight-based LiDAR cannot collect data with a high sampling rate; (2) the applicability of the phase-shift-based LiDAR is limited to a short range below several hundred meters; (3) special surface treatment is often necessary for LDV; and (4) the use of high-power pulse laser may have implications associated with eye safety. However, the developments and improvements of not only hardware devices but also damage detection algorithms will inevitably contribute to the fast and accurate health assessment of earthquake-affected structures and prevent further catastrophic failures.

(nonlinear) response in selected components of the structural frame. Such response is associated with structural damage that produces direct (capital) loss repair cost, indirect loss (possible closure, rerouting, business interruption), and perhaps casualties (injuries, loss of life) (Constantinou et al. 2007b).

There are various mechanisms/devices that have been invented in the past for the protection of structures from the damaging effects of earthquakes. A lot of these devices are based on the idea of uncoupling the structures from the ground. Rollers, layers of sand, or similar materials are among the ideas proposed in the past to allow a building to slide. Such mechanisms are early versions of the now widely accepted and applied concept of base/seismic isolation (Kelly 2004).

Lead-rubber bearings are one of various existing types of seismic isolation devices and have been used for years for the protection of structures from the damaging effect of earthquakes. This entry presents summarized information regarding the use, benefits, properties, and applications of lead-rubber bearings along with literature sources for further reading on the subject.

Lead-Rubber Bearings with Emphasis on Their Implementation to Structural Design

Base isolation; Bridge bearings; Elastomeric bearings; Lead-plug bearings; Lead-rubber bearings; Rubber bearings; Seismic isolation

Introduction

The seismic design of conventionally framed bridges and buildings relies on the dissipation of earthquake-induced energy through inelastic

Seismic Isolation

The concept of base isolation is quite simple. The seismic isolation system is a group of low-stiffness elements that is placed between the foundation and the structure and reduces the effects of the earthquake on the latter. Use of these elements causes a decrease of the fundamental frequency of the structure shifting it away from both its fixed-base frequency and the predominant frequencies of the ground motion (Kelly 2004).

Seismic isolators are typically installed between the girders and bent caps (abutments) in bridges and the foundation and first suspended level in a building. Fig. 1 (Constantinou et al. 2007b) shows a typical bridge installation of seismic isolators; the isolators were installed at the top of the pier as shown in Fig. 1b (the steel plate on the side of the isolator is part of the lateral wind-restraint system). For bridge

bridge (Constantinou et al. 2007b). (a) Bridge elevation. (b) Friction pendulum seismic isolator

Lead-Rubber Bearings with Emphasis on Their Implementation to Structural Design, Fig. 2 Concept of seismic isolation (Constantinou

et al. 2007b). (a) Decrease in spectral accelerations. (b) Increase in spectral displacements

construction, the typical design goals associated with the use of seismic isolation are (a) reduction of forces (accelerations) in the superstructure and substructure and (b) force redistribution between the piers and the abutments (Constantinou et al. 2007b). Reduction of forces is achieved through the aforementioned structural frequency shift as shown in Fig. 2a (Constantinou et al. 2007b). Control of the increase in displacements that results from the use of seismic isolation is achieved through introducing damping (energy dissipation) in the isolator as shown in Fig. 2b (Constantinou et al. 2007b).

There are various types of seismic isolation devices, including but not limited to: (a) elastomeric-based systems, (b) low-damping natural and synthetic rubber bearings, (c) high-damping natural rubber (HDNR) systems,

(d) isolation systems based on sliding, (e) friction pendulum system, (f) double and triple concave friction pendulum sliding bearings, (g) spring-type systems, and (h) lead-rubber bearings (Kelly 2004, Constantinou et al. 2007b). Elastomeric bearings (low- and high-damping rubber, lead rubber) and sliding bearings (spherical sliding or friction pendulum bearings, flat sliding or EradiQuake bearings) are the two common types of seismic isolation bearings used in the United States (Constantinou et al. 2007b).

Lead-Rubber Bearings: Short Description and Historical Background

The lead-rubber bearing (LRB) was invented in 1975 by W. H. Robinson in New Zealand (Skinner et al. 1993; Kelly 2004; Robinson and Tucker 1977, 1983). It has been extensively used

Lead-Rubber Bearings with Emphasis on Their Implementation to Structural Design, Fig. 3 Lead-rubber bearing construction details (Constantinou et al. 2007b)

in New Zealand, Japan, and the United States (Kelly 2004). Such bearings have been used to isolate many buildings, and buildings using them performed well during the 1994 Northridge and 1995 Kobe earthquakes (Kelly 2004). A short summary of the response of one of these buildings during the 1994 Northridge earthquake is provided in the next section.

Generally, a lead-rubber bearing is composed of a low-damping (unfilled) elastomer and one (typically) or more (less common) lead cores. A cutaway view of a lead-rubber bearing is illustrated in Fig. 3 (Constantinou et al. 2007b). In this illustration, the separate components of the bearing can be seen clearly: (a) the lead plug in the core of the bearing, (b) the end and flange plates on top and bottom of the bearing, and (c) the low-damping elastomer with alternating rubber layers and steel shim plates.

The elastomer rubber layers serve as the “isolation” (i.e., stiffness and fundamental structural frequency reduction) component; lead also contributes to the stiffness of the bearing, but this contribution is relatively minor. The steel shim plates assist with vertical load support. The lead core mainly serves as the “damping” (i.e., energy dissipation) component. A typical hysteretic (force-displacement) loop for a lead-rubber bearing is shown in Fig. 4 (Constantinou et al. 2007b).

The lead core provides excellent energy dissipation capability under confined conditions. Such conditions can be achieved by constructing the

Lead-Rubber Bearings with Emphasis on Their Implementation to Structural Design, Fig. 4 Hysteretic energy dissipation in lead-rubber bearings (Constantinou et al. 2007b)

plug slightly (less than 5 %) longer than the height of the rubber bearing and connecting the top and bottom flange plates to the rubber bearing end plates through countersunk bolts. Then the plug is compressed upon bolting the flange plates to the end plates; it expands laterally and wedges into the rubber layers between the shim plates. The magnitude of energy dissipation capacity depends on the lead plug diameter (Constantinou et al. 2007b).

Example: Performance of a LRB-Isolated Building During the 1994 Northridge Earthquake

As an example of the benefits from the use of lead-rubber bearings, a brief summary of the behavior of the LRB-isolated University of Southern California Teaching Hospital during the 1994 Northridge earthquake is provided in this section. A very detailed description has been outlined by Kelly (2004). Design and construction details of this building have been described by Asher and Van Volkinburg (1989), Asher et al. (1990), and KPFF Consulting Engineers (1991).

The hospital is an eight-story concentrically braced steel frame with significant irregularities in its plan and elevation. The isolation system consists of 68 lead-rubber isolators and 81 elastomeric isolators. The lead-rubber bearings are distributed in the perimeter of the building under the braced frames to minimize torsional response in the isolated structure. Elastomeric bearings are used in the interior.

The fixed-base period of the superstructure is approximately 0.7 s. The design base shear of the hospital is 0.15 g, while the design corner bearing displacement including torsion is 26.0 cm. The effective period of the isolation system at this displacement is approximately 2.3 s.

The strongest motions recorded at the site were in the north–south direction. The pseudo-acceleration response spectrum of the north–south foundation motion (Clark et al. 1996) shows significant short-period energy in the range of 0.2–0.6 s, but relatively little energy above a period of approximately 1.3 s. At periods greater than 2 s, the corresponding 10 % damped spectral displacement is less than 3 cm.

The isolation frequency due to the north–south acceleration was approximately 0.7 Hz and the damping ratio approximately 14 %. In the east–west direction, the isolation frequency was 0.75 Hz and the damping ratio was 13 %. The isolation system performed well, its damping capacity was good, and the structure was effectively isolated from the earthquake ground motions. It is noted that the Northridge earthquake caused significant damage to other buildings in the medical center (Kelly 2004).

Entry Roadmap

Section [Introduction](#) of this entry has presented a brief introduction, description, historical background, and an application of lead-rubber isolators. The following sections of this entry are outlined below.

Section [Lead-Rubber Bearing Properties and Structural Design](#) provides a more detailed description of the properties of lead-rubber

bearings along with their significance in structural design.

Section [Applications](#) provides a few more examples of lead-rubber bearing applications in buildings, bridges, and structure retrofit.

Section [Summary](#) is a summary of this entry.

Section [Cross-References](#) provides a list of related entries from this Encyclopedia.

Section [References](#) provides a list of references used in this entry.

Lead-Rubber Bearing Properties and Structural Design

A brief description of lead-rubber bearings and their components has been provided in section [Introduction](#). This section provides further details regarding the properties of lead-rubber bearings.

An idealized force-displacement loop for a lead-rubber bearing is shown in Fig. 5 (Constantinou et al. 2007b) with its significant parameters/mechanical properties being the characteristic strength, Q_d , and the post-elastic stiffness, K_d , defined as follows:

$$Q_d = A_L \sigma_L \quad (1)$$

$$K_d = \frac{f_L G A_r}{T_r} \quad (2)$$

where f_L is a parameter that represents the effect of the lead core on the post-yield stiffness (typically close to unity), A_L is the cross-sectional area of the lead core, T_r is the total thickness of the rubber layers, G is the shear modulus of

Lead-Rubber Bearings with Emphasis on Their Implementation to Structural Design,

Fig. 5 Idealized force-displacement relation of a typical seismic isolation system (Constantinou et al. 2007b)

Lead-Rubber Bearings with Emphasis on Their Implementation to Structural Design, Table 1 Lead-rubber bearing components/properties and environmental/other effects

Property	Controlling component	Component significance
Post-elastic stiffness, K_d	Elastomer (typically low-damping rubber)	Structure stiffness reduction Structure fundamental frequency reduction
Characteristic strength, Q_d	Lead core	Energy dissipation
Environmental or other factor	Component/property	Effect
Aging	Elastomer/post-elastic stiffness, K_d	Minor increase
	Lead/characteristic strength, Q_d	Insignificant (lead yield strength not affected by aging); confinement changes may affect strength slightly
Temperature	Elastomer/post-elastic stiffness, K_d	Increase for low temperatures; effect depends on exposure duration; elastomer becomes brittle below glass transition temperature (compound dependent, -55°C for natural rubber)
	Lead/characteristic strength, Q_d	Increase/decrease for temperature decrease/increase (the same happens to lead yield strength)
Heating	Elastomer/post-elastic stiffness, K_d	Insignificant
	Lead/characteristic strength, Q_d	Strength drops significantly, especially during the first few cycles and for high-frequency and large-amplitude motion due to lead core temperature increase; strength recovers its original value after lead core is allowed to cool down
Cumulative travel	Elastomer/post-elastic stiffness, K_d	None
	Lead/characteristic strength, Q_d	Low speed strength increase after high-amplitude cumulative travel; none in all other cases

rubber, A_r is the bonded rubber area (i.e., excluding the outer rubber cover beyond the steel shims), and σ_L is the effective yield stress of lead (Constantinou et al. 2007b).

The elastomer has a shear modulus between 65 and 100 psi at 100 % rubber shear strain. The lead core has a diameter ranging between 15 % and 33 % of the bearing bonded (i.e., distance between the outer edges of the shim plates) diameter. The maximum shear strain range for LR bearings varies depending on the manufacturer but is generally between 125 % and 200 % (Constantinou et al. 2007b). The effective yield stress of lead typically ranges between 10 and 20 MPa (Skinner et al. 1993; Constantinou et al. 2007b).

Numerous tests and studies have been conducted to investigate and determine how these properties are affected by environmental and other factors such as aging, temperature, heating, history of loading, etc., and modification factors for these properties have been proposed

(Constantinou et al. 1999, 2007a, b; Kalpakidis and Constantinou 2009a, b; Kalpakidis et al. 2010). Some of these effects and a summary of lead-rubber bearing properties and components along with the significance of these components are outlined in Table 1.

A theoretical interpretation of the effects of seismic isolation on the dynamic properties and, consequently, on the dynamic behavior of a structure has been performed by Kelly (1990; 2004) through the use of a simplified two-degree-of-freedom (2-DOF) model. This simplified model treats the superstructure as a single-degree-of-freedom (SDOF) system that has appropriate period, stiffness, damping, and mass values. This SDOF system representing the superstructure is on top of a mass (equal to the base mass) which in turn is on top of the isolation system (defined by appropriate stiffness and damping values).

Assuming a very wide separation (order of 10^{-2} to 10^{-1}) between the square of the isolation

frequency (i.e., frequency of the combined isolation-superstructure system when the superstructure is rigid) and the square of the fixed-base frequency of the superstructure, as well as a value with a 10^{-2} to 10^{-1} order of magnitude for both of the respective damping ratios, the resulting two modes for the combined superstructure-isolation system (simplified 2-DOF model) have the following characteristics (Kelly 1990, 2004):

- Isolation frequency/mode 1: The frequency is affected very slightly by the flexibility of the superstructure. The mode shape involves very little structural deformation (the structure is nearly rigid), while the isolation system picks up much more deformation.
- Structural frequency/mode 2: The mode shape involves much more structural deformation than the first mode, but its effect is insignificant due to the very small participation factor associated with this mode.

In short, as mentioned earlier in this entry, the presence of a seismic isolation system (with either lead-rubber bearings or other types of isolators) is beneficial because it increases the fundamental period of the superstructure (i.e., decreases the corresponding spectral acceleration) while at the same time it adds an energy dissipation mechanism to the system.

Applications

This section contains a brief summary of example applications of lead-rubber bearings (a building application has been briefly described in section [Example: Performance of a LRB-Isolated Building during the 1994 Northridge Earthquake](#)). It is noted that each example herein is merely a high-level summary of an application. For further details, the reader is referred to the respective sources provided for each example.

Richmond–San Rafael Bridge (Retrofit)

In general, use of seismic isolation can reduce forces in bridge foundations by up to 70 %. Isolated bridges are superior in performance, and

their cost is lower than that of non-isolated bridges ([DIS, Inc.](#)).

The Richmond–San Rafael Bridge is the northernmost east–west crossing of the San Francisco Bay in California. It connects Richmond (east end) to San Rafael (west end). It opened in 1956, at which time it was one of the longest bridges in the world. Its length is 5.5 miles and it spans two principal ship channels. In the fall of 2001, extensive seismic retrofit work was performed along with necessary age-related maintenance. The retrofit was completed in 2005.

The bridge structure has a characteristic shape shown in Fig. 6 that has been described as “roller coaster span” and “bent coat hanger.” Without the use of seismic isolators, shorter and stiffer piers would attract most of the lateral load. 55-in. diameter lead-rubber isolators were used for the retrofit. The benefit from using isolators was lateral load redistribution throughout the structure ([DIS, Inc.](#)).

San Francisco City Hall (Retrofit)

The City Hall was built in the late 1800s and was destroyed in the 1906 San Francisco earthquake. It was subsequently rebuilt at a nearby location and reopened in 1915. The City Hall was again damaged in the 1989 Loma Prieta earthquake. Subsequently, seismic retrofit work was performed and the building was reopened in 1999.

For the seismic retrofit, the two-block-long building was cut from its foundation and made to “float” on more than 500 lead-rubber isolators, designed to dissipate seismic energy and to allow the building to sway horizontally up to 26 in. without shaking apart ([MCEER](#)). A photo of the building can be seen in Fig. 7.

Oakland City Hall (Retrofit)

Construction of the Oakland City Hall was completed in 1914. A photo of the building can be seen in Fig. 8. The structure was the first high-rise government office building in the United States (Walters 2003). It is an 18-story building with full basement. Its podium contains a central rotunda, council chambers, and administration offices. An office tower is above the podium, and a clock tower is above the office tower ([MCEER](#); Walters 2003). The structure suffered extensive damage in

the 1989 Loma Prieta earthquake, losing about 20 % of its strength in the north–south direction and 30 % in the east–west direction (Walters 2003).

Subsequently, several studies were performed resulting in seismic isolation retrofit work that was completed in 1995 (Walters 2003). 42 lead-rubber bearings and 69 natural rubber bearings were utilized for the retrofit (MCEER).

The main reason for selecting seismic isolation as the retrofit method (instead of other

conventional strengthening methods) was the fact that the existing structural system of the City Hall (riveted steel frames with infill masonry) could provide sufficient lateral strength and stiffness only until the development of cracks. After cracks develop, the response would degrade under repeated cyclic loading (Benjamin and Williams 1958, Walters 2003). The result would be lack of ductility and of reliable post-cracking strength, which would require

Lead-Rubber Bearings with Emphasis on Their Implementation to Structural Design,

L

a nearly elastic resistance of maximum earthquake forces (Walters 2003). The most effective way to satisfy this demand would be the use of seismic isolation that would significantly reduce the seismic forces acting on the structure.

Emergency Headquarters at Fukushima Daiichi Nuclear Power Plant (New Construction)

During the July 2007 Niigataken Chuetsu-oki earthquake (M6.8), there was no damage to the safety of nuclear power plant facilities at TEPCO Kashiwazaki-Kariwa Nuclear Power Plant. The reactors were shut down safely. In addition, the Emergency Headquarters located on the first floor of the office building suffered little structural damage. However, minor damage (such as door lock failure, overturning of racks, sanitary system trouble, etc.) disrupted the emergency response (Hijikata et al. 2012; TEPCO 2007).

Subsequently, TEPCO decided to use base isolation in “Emergency Headquarters” buildings at every nuclear power plant site. One such building

was constructed at the Fukushima Daiichi site in March 2010. The isolation system consisted of four lead-rubber bearings at the corners, 10 natural rubber bearings at the perimeter, 31 sliding bearings, and 16 oil dampers (Hijikata et al. 2012).

The building suffered no damage from the Great East Japan earthquake of March 2011 (Hijikata et al. 2012).

Summary

This entry has presented an overview of the behavior, properties, and applications of lead-rubber seismic isolation bearings.

Seismic hazard mitigation resulting from the use of lead-rubber bearings is twofold. First and foremost, these devices lengthen the structural period and thus decrease the seismic demand on the structure. In addition, they absorb a portion of the seismic energy.

Lead-rubber bearings have been used to isolate many buildings, and buildings using them

performed well during strong earthquakes including the 1994 Northridge and 1995 Kobe earthquakes (Kelly 2004) and the 2011 Great East Japan earthquake (Hijikata et al. 2012). Benefits from their use are numerous. Applications include newly constructed buildings and bridges as well as retrofit of existing buildings and bridges. A very significant benefit from the use of lead-rubber bearings for seismic retrofit, other than the (obvious) mitigation of seismic hazard, is the cost-effective preservation and seismic upgrade of historic buildings and other old architecturally and culturally significant structures.

Additionally, benefits from using lead-rubber bearings in high-importance structures are tremendous. Such structures (e.g., bridges, hospitals, government buildings) are expected to resume their normal operation immediately after an extremely strong earthquake. Seismic isolation serves as an additional means to that scope. This benefit is even more evident in high-importance structures the destruction of which would mean not only disruption of crucial service (e.g., transportation, health care, energy production) but also potential health hazard for whole communities (nuclear power plants, chemical plants, etc.).

Introduction

The United Nations International Strategy for Disaster Reduction (UNISDR) defines disaster as the “serious disruption of the functioning of a community or society involving widespread human, material economic or environmental losses and impacts, which exceeds the ability of the affected community or society to cope using its own resources” (UNISDR 2014). The idea of learning, from earthquake disasters, to reduce the risks associated with future earthquakes is widely held around the world and across a range of sectors. The United Nations defines disaster risk reduction as the “concept and practice of reducing disaster risks through systematic efforts to analyse and manage the causal factors of disasters, including through reduced exposure to hazards, lessened vulnerability of people and property, wise management of land and the environment, and improved preparedness for adverse events” (UNISDR 2014). The research sector has traditionally contributed to these efforts according to discipline. The physical sciences identify the causes and probability of earthquake hazards and relevant branches of engineering focus on mitigating the impact of earthquakes on the built environment, while the medical and social sciences research a range of human impacts, in socioeconomic, political, and cultural spheres and measures to address them.

The growing emphasis on risk reduction, however, is creating a demand for integrated research approaches that focus directly on contributing to disaster mitigation initiatives. The US Earthquake Engineering Research Institute (EERI), for example, aims to integrate engineering with physical and social science initiatives and so reduce earthquake risk by (1) advancing the science and practice of earthquake engineering; (2) improving understanding of the impact of earthquakes on the physical, social, economic, political, and cultural environment; and (3) advocating comprehensive and realistic measures for reducing the harmful effects of earthquakes (EERI 2014).

UNISDR has also stressed the importance of more multidisciplinary, problem-solving

approaches to disaster risk reduction, warning that such initiatives will require better mechanisms “for integrating science and technology into policy processes” and “for bridging the gaps between environmental, humanitarian, development and governmental actors” (UNISDR 2014).

This emphasis on increased coordination between disciplines, scientific and policy domains, and between global sectors is informed, in turn, by a growing perception that existing knowledge is *not* being translated into effective disaster risk reduction measures. The 2009 Science Plan for Integrated Research into Disaster Risk (IRDR), for example, is a response to concern that “the widening gap between advancing science and technology and society’s ability to capture and use them” is a major factor in rising global disaster losses (ICSU 2008). Jointly sponsored by UNISDR, the International Council for Science (ICSU), and the International Social Science Council (ISSC), this plan aims to foster a better understanding of the processes involved in the translation of “research findings about natural hazards and human behavior” into practices and policies that are “effective in minimizing the human and economic costs of hazards” (ICSU 2008, p. 5, 7).

This Science Plan draws on White et al.’s seminal 2001 review of trends in the hazard and disaster field. Explicitly couched as an investigation of the relationship between increasing disaster losses and the science that could have been expected to slow, arrest, and reverse that rate of increase, this review began with a series of questions: “Is human knowledge and understanding of the causes of the losses inadequate despite the research effort, or is it that existing knowledge is not applied, or not used in an effective fashion? Could there be other explanations that lie outside our scholastic assumption that knowledge has a key role to play?” (White et al. 2001, p. 81).

Finding that the preceding decades had featured increasing convergence in the literature concerning broader causal factors, White et al. concluded that the lack of knowledge explanation was unlikely. Instead the evidence they

draw from this field suggested that existing scientific knowledge had either not been applied at all or had not been applied effectively. In addition, they found that global patterns of unsustainable development had also contributed to rising disaster losses (White et al. 2001).

This encyclopedia chapter is largely concerned with research into the broader, *collective* learning processes and pathways found to have been involved in the translation of scientific knowledge into earthquake disaster risk reduction policy, as well as into challenges to such learning. The first section begins with examples taken from US disaster policy research that are directly concerned with the translation of research findings into policy and practice after disaster events. Using social learning policy approaches, this work has confirmed that earthquake and other disasters have had a focusing effect on policy agendas in the US. Higher-level support, policy frameworks that facilitate risk reduction, increasingly networked global communities, and multilateral learning networks have been found to be key factors in learning disaster risk reduction lessons after major events. These US examples are followed by an example from New Zealand, in which learning from an earthquake disaster has informed an all-hazards risk reduction approach and a policy framework that has devolved responsibility for risk reduction to local levels.

Where the first section is concerned with research focused on the opportunities that contemporary developments offer for disaster risk reduction, the second section turns to consider the inhibiting effects the same developments have had on disaster risk reduction. Outlining evidence of barriers to consensus building both within and across disciplines, sectors, and domains, it also touches on data management issues associated with recent technological and social developments. The article concludes with a brief discussion of the larger global issues that have been found to be associated with the distribution of vulnerability to disasters, unsustainable development, the emergence of subgovernment policy communities, and the emerging focus on major disasters and risk.

Largely limited to considerations of *broader collective learning processes*, the focus is schematic, rather than comprehensive, and so leaves significant research outside the immediate frame. For a comprehensive review of the current wider hazard and disaster research landscape, readers are referred to White et al.'s elegant 2001 account. The rich body of work concerned with historical and other understandings of lesson learning after earthquake disasters also falls largely outside scope, as does extensive recent progress in understanding the psychological and other processes involved in decision-making by individuals.

Finally, a brief clarification concerning the tone of this entry, and expectations as to audience. The expectation for the encyclopedia entry is that the majority of its readers are unlikely to be familiar with the field. Accordingly current findings in the relevant topic area are conveyed as clearly as possible for a wider disciplinary audience. This particular field is often divided, particularly over the significance of the extension of governance to include social actors and current emphases on consensus and risk reduction. Such debates are understood to be integral to the production of knowledge and, where relevant to the focus of this entry, are conveyed as evenhandedly as possible. The field is also characterized by densely logical argument, the comprehensive referencing of influences, carefully defined terminology, and painstaking attention to the detail, diversity, and complexity of subject matter. For reasons of scope, and in the interests of clarity, the following comparatively brusque reduction of this diverse wider body of work to a few broad findings runs counter to these hallmarks. References are provided for those who wish to pursue the arguments in more depth.

Translating Science into Policy and Practice

It is widely acknowledged that disaster risk reduction is the responsibility of national governments and needs to be effected at local levels (UNISDR 2014; Global Network 2013). Recent

global developments, however, have impacted on political authority at both national and local levels. Economic integration and market liberalism have limited the authority of governments over multinational economic actors, global bodies are able to impose political requirements on nation states that often conflict with the demands of their constituents, and information and communication technologies have facilitated both global economic transactions and transnational networks of civil society actors (Skogstad 2003). This has contributed to an increase in expert and market-based authority, at the expense of democratic process, as governments respond to an increasingly complex and fragmented policy-making environment by turning to these and other sectors for resources and cooperation (Skogstad 2003, 2005). But at the same time, increased appetite for public participation – fuelled by transnational networks of civil society actors – has also contributed to an international trend of greater public involvement in policy formation, so offering the potential, at least, for new forms of democratic process (Rowe and Frewer 2005; Skogstad 2003).

As a result, a large part of policy making in industrial societies is now carried out collaboratively by government officials, scientific and other experts, and public representatives, through “decentralized, and more or less regularized and coordinated, interactions between state and societal actors” (Skogstad 2005). As a means “to coordinate resources of information, support and authority across state and non-state actors,” this subgovernment sphere has been recognized to have the potential to provide “more effective government, and arguably... more legitimate government” (Skogstad 2005). This section is concerned with research that has focused on the *opportunities* for earthquake risk reduction in the United States and New Zealand that have been provided by these changes.

Higher-Level Coordination in the US Earthquake Policy Domain

US policy theorists interested in the role of technical information in policy making have responded to these changes in the political

environment and to emerging complexity theory, by focusing on the wider influences on the policy process over time. In particular, this expanded focus includes all actors who regularly and actively attempt to influence public policy concerning a particular issue or problem. Collectively described as policy subsystems, communities, networks, or domains, these larger groupings have been found to typically manifest (one or more) advocacy coalitions (Skogstad 2005; Birkland 1998; Sabatier 1998). Usually including actors from a range of government and other organizations and interest groups, this kind of coalition has been found to be held together by shared beliefs about the relevant policy issue. By engaging “in coordinated activity over time,” advocacy coalitions have been found to influence policy outcomes (Sabatier 1998). It has been widely recognized, however, that major policy changes have not been caused solely by the activity of such coalitions. Instead, these policy changes only happen when external factors create a much wider perception that the existing policy has *failed*. Equally, although necessary, this wider consensus has not been found sufficient in itself to trigger major shifts in policy (Birkland 1998; Sabatier 1998).

The Focusing Effect of Earthquake Disasters

The only significant application of this theory in the earthquake risk reduction context is Birkland’s (1998) influential comparative study of four US disaster policy domains between 1960 and 1990. This project compares all congressional hearing testimony concerning earthquake, hurricane, oil spill, and nuclear accident disasters over this 30-year period. It was designed to test the idea that “sudden, attention-grabbing events, known as focusing events,” could advance issues on the relevant policy agenda and – by contributing to the perception that existing policy had failed – potentially trigger major changes in risk reduction policy (Birkland 1998). Birkland established that major US earthquake events between 1960 and 1990 had had a significant focusing effect on the congressional earthquake policy agenda. After each major event, the dominant topic on the policy agenda changed, the

volume of earthquake testimony increased, and much more of this post-event testimony was critical of existing policy. Testimony that referred to specific earthquake events was also much more likely to be critical of existing policy than other earthquake testimonies (Birkland 1998). This contributed to the much wider consensus concerning the need for major change to earthquake risk reduction policy that led to the 1977 National Earthquake Hazard Reduction (NEHR) Act (Birkland 1998).

Birkland’s (1998) research also established that the focusing effect of major events was much greater in the earthquake domain than in the other three disaster domains. The comparison between congressional testimony in the oil spill and nuclear power plant accident policy domains indicated that such differences were likely to be related to disaster coverage (Birkland 1998). Major nuclear accidents had had little impact on the volume or tone of congressional testimony, which continued to feature a deadlock between the powerful industry lobby and those opposed to it. By contrast, the high-profile Exxon Valdez disaster triggered the resolution of a similar 14-year deadlock between the oil industry and environmental advocacy groups, by way of the major policy change enacted through the 1990 Oil Pollution Act (Birkland 1998). Birkland (1998) found that the ambiguity of the harm caused by nuclear accidents contributed to their lack of focusing effect. Unable to be visually conveyed to the public, this harm was open to scientific dispute, unlike the dramatic footage of oil-soaked beaches and struggling wildlife following the Exxon Valdez disaster.

Coordinated Scientific/Political Advocacy

Testimony in the earthquake policy domain revealed that the 1977 NEHR Act was drafted and enacted by a very active coalition of senior scientists, academics, and government officials, who had come together over the preceding 15 years to lobby congress for changes to the existing earthquake policy (Birkland 1998). Coalescing around a shared commitment to science-based earthquake risk reduction, this group dominated the wider policy community involved in

congressional earthquake hearings and policy formation between 1960 and 1990. After the 1964 9.2 Alaskan and the 1971 6.6 San Fernando events in particular, this coalition was responsible for authoritative critiques of existing policy in congressional science committee hearings (Birkland 1998; Hamilton 2003).

This distinguished the earthquake policy domain from the hurricane domain over the same period, which continued to be dominated by local governmental interests pushing for disaster relief and engineered solutions to hurricanes. Although prominent researchers and officials had warned of the need for hurricane mitigation over this period, they had not succeeded in activating a multi-sectoral coalition that lobbied “for improved federal policy to deal with hurricanes in *testimony before the Congress*” (Birkland 1998; emphasis original). Where the earthquake agenda featured a mix of mitigation and disaster relief policy and was usually heard in congressional science committees, the majority of hurricane testimony concerned disaster relief and was heard in congressional public works committees, where mitigation was subordinate to local distributive spending on disaster relief and public works projects (Birkland 1998).

Higher-Level Coordination of Disciplinary and Agency Fragmentation and Competition

The translation of science into policy in this US earthquake disaster domain thus required that the scientific community became politically active and forged alliances within the government sector, first in pushing for changes to policy and then in drafting and jointly enacting these changes. This was a complex and extensive process, however, which involved as much competition as it did consensus building, both within and between scientific and government spheres.

After the 9.2 1964 Alaskan earthquake drew attention to potential earthquake risk in the US, for example, several major earthquake research centers were established which then “competed vigorously to stake out a lead-agency position for earthquake research” (Hamilton 2003). Over the same period three high-level reports proposing

competing national earthquake research programs were presented to congressional committees in 1965, 1968, and 1969 by agencies representing seismological, geological, and engineering interests, respectively. By 1970, “competition among the disciplines and between the agencies, combined with the waning concern after the Alaskan earthquake, contributed to a lack of budgetary attention to the earthquake threat.” (Hamilton 2003).

Then on 9 February 1971, the 6.6 San Fernando earthquake caused 65 fatalities and spectacular footage of collapsed freeway overpasses and hospitals. Renewing both public and high-level political interest in the issue, this event led to federal reforms merging relevant agencies, at the same time as renewed congressional activity led to the 1977 NEHR Act (Hamilton 2003; Birkland 1998). A sequence of further changes to the Act established the NEHR Program (NEHRP), formalizing the role of the advocacy coalition and addressing the fragmentation and competition that had characterized this domain by integrating all earthquake-related disciplines, policy, and practice into a single coordinated program (Hamilton 2003). Responsible for policy formation and for funding and coordinating a range of research programs, this high-level multilateral initiative continues to include US federal agencies responsible for emergency response (Federal Emergency Management Association [FEMA]), standards and technology (National Institute of Standards and Technology [NIST]), and for both academic (National Academy of Sciences [NAS]) and government research (United States Geological Survey [USGS]). The directors of these agencies, together with those of the White House Office of Science and Technology Policy (OSTP), and the Office of Management and Budget (OMB) make up the NEHRP Interagency Coordinating Committee (ICC) (NEHRP 2014).

This research into the US earthquake policy domain established that scientific findings concerning earthquake risk reduction have been translated into policies and practices through complex, high-level processes that have extended well beyond decision-making interactions

between individual scientists and policy makers. Key factors included:

- A political environment in which governance structures were being extended to include non-state actors, through emerging subgovernment networks responsible for drafting and implementing policy
- High-profile earthquake disasters, which triggered a widespread consensus that policy change was required – lessons really have been learned *from* earthquake events
- A politically active scientific community, able and open to forming the ongoing coalitions required in the formation of such networks and committed to using the focusing effect of disasters to push for policy change
- Ongoing high-level political intervention to reduce disciplinary and government sector fragmentation and competition, by creating an integrated national earthquake risk reduction coordinating program.

Disaster Risk Reduction Policy and Practice: Coordination at Local Levels

Research into the role of policy subsystems in disaster risk reduction has not been restricted to higher-level changes to policy. Others have focused on such activity at the local level. Busenberg (2000), for example, has studied the local policy subsystem that emerged in Alaska after the 1989 Exxon Valdez disaster. The 1990 Oil Pollution Act (OPA) provided for a Regional Citizens Advisory Council (RCAC) to oversee environmental risk management in the region, legislating a permanent role for the advocacy coalition involved in its design and implementation (as did the 1977 NEHR Act) (Birkland 1998). Guaranteeing the independence of the RCAC, the 1990 OPA requires the oil industry to fund the operations of this body for as long as the Alaskan Pipeline remains in operation. The RCAC has 19 member organizations. These include a range of local interest and local government groups, each with a representative on the Board of Directors; five issue-specific committees include board members, experts, and local citizens.

Busenberg focused on the innovative learning arrangements that brought the RCAC into the wider, multilateral policy network involved in significant policy decisions concerning the environmental management of the industry in the region (Busenberg 2000). Between 1990 and 2000, these decisions resulted in policy changes that significantly reduced the risk of future oil spill disasters. This included legislation requiring a sophisticated local weather forecasting system, an integrated regional marine firefighting service, and supported tanker navigation (including redundant tug capacity) within Prince William Sound. The first of these initiatives was immediately enacted, while the latter two required supporting evidence established by research programs partially or completely funded by the RCAC (Busenberg 2000).

Social Learning in Relation to Other Theories of Learning and Participation

Busenberg and Birkland are both working within the social learning policy theory tradition. For both, the term “learning” does not simply refer to an increase in knowledge but is rather defined in relation to policy change. Busenberg has distinguished the incremental, ongoing local-level policy learning that he traces over 10 years in Prince William Sound from the larger changes in policy after major events, which interests Birkland. The coordination and consensus building process is, however, very similar, and both researchers define the social learning process in relation to policy outcome. Busenberg finds that local, incremental learning within the relevant networks of organizations and individuals occurred only when initiatives gained enough support from key stakeholders to be *enacted as risk-reducing policy change*. In the case of supported tanker navigation, this learning had required a higher-level intervention from the state governor. By contrast, initiatives that were researched and promoted but were not enacted in policy are interpreted as evidence that, in these cases, social learning did *not* occur. Similarly, Birkland defines social learning with reference

to evidence of policy outcome: “Policy learning can be identified if there is *prima facie* evidence of policy changes that are reasonably linked to the causal factors that connected the event under consideration to its harms, and if addressing these factors would be likely to mitigate the problem” (Birkland 2009).

The social learning process explored by these and other policy theorists is described as social because it is not restricted to individuals, or organizations, or even sectors, but relies on a *much wider social consensus* concerning the failure of existing policy. It is understood to be a learning process in part because it draws from other learning theories that also feature this negatively driven sequence, in which previously unexamined assumptions are understood to have failed, and so triggered a new set of assumptions. Informed by both Kuhn’s scientific theory of paradigm shifts and so-called double-loop organizational learning theory, for example, social learning theory also relies on the punctuated equilibrium pattern identified by complexity theory as that in which complex human, social, ecological, and biological systems learn by adapting to disruption. Equally, for most of these theorists, the activities of policy subsystems are described as learning because they *increase knowledge* concerning both the policy problem and likely outcomes of policy alternatives (Sabatier 1998). The emphasis on improved policy outcomes, however, is distinct to Busenberg and Birkland’s application of this approach to disaster risk reduction policy.

It is useful to clarify the relationship between this social or policy learning framework and similar concepts current in the hazard and disaster context. A variety of closely related learning arrangements have been recently reviewed by Voorberg et al. (2013). Covering a variety of disciplines, this review finds the terms social innovation, knowledge co-creation, or knowledge coproduction are all used to describe what appears to be the same broad learning process (note that their review does *not* include constructivist uses of the term knowledge coproduction, which refer to the mutually constitutive relationship between

science and society). This embedded process takes place in a specific local and institutional context, in which relevant stakeholders participate and collaborate across organizational boundaries and jurisdictions, engaging in interactive exchanges of knowledge, information, and experiences through intra- and interorganizational networks (Voorberg et al. 2013). To this extent, the social learning process constitutes a particular variant of this collaborative learning process. However, Voorberg et al. (2013) found that irrespective of discipline, the focus is almost entirely restricted to considering the process, and value, of such participation, rather than its outcomes, if any. By contrast, the social learning process researched by Birkland and Busenberg is defined in relation to policy outcome.

Secondly, it is also useful to relate the social learning policy process to the international trend of greater public and community involvement in policy formation. Such participation is recognized to be an essential component of any strategy designed to increase community resilience to disasters. In a review of relevant literature, Rowe and Frewer (2005) found more than 120 types of public participation described. They distinguish between communication, consultation, and participation, in order to develop a useful typology (Table 1).

According to this typology the RCAC studied by Busenberg can be seen as a *participatory mechanism* of public engagement – although established as a council, the focus on oil spill disaster risk reduction puts it in the task force category: the use of “a small group of participants (public representatives) with ready access to all pertinent information, to solve specific problems” (Rowe and Frewer 2005). Congressional hearings, however, largely constitute a public *communication mechanism*. The social learning that concerns Busenberg and Birkland does thus rely on forms of public engagement. Their focus, however, is not on public engagement per se, but rather on the larger policy process, including all events and factors that influence policy design and enactment; again, their emphasis is on the policy outcome.

Learning from Earthquake Disasters, Table 1 Mechanisms of public engagement (Adapted from Rowe and Frewer 2005)

Engagement mechanism	Examples	Characteristics
Communication		Information to -> public
Communication type 1	Traditional “publicity”	Controlled selection; targets particular population with set information
Communication type 2	Public hearings, seminars, etc.	Rely on public initiative, provide flexible information
Communication type 3	Drop-in centers, website information	Rely on public initiative; provide set information (even if FTF)
Communication type 4	Hotlines	Rely on public initiative; uncontrolled selection/flexible information
Consultation		Information from <- public
Consultation type 1	Opinion poll, survey, referendum, etc.	Large samples – specific questions; controlled selection/ closed response
Consultation type 2	Consultation document	Open responses on specific issues – controlled selection
Consultation type 3	Electronic consultation – interactive website	Open responses on specific issue – uncontrolled selection
Consultation type 4	Focus group	Emphasis on information quality; open responses, controlled selection
Consultation type 5	Study circle	Emphasis on information quality; open responses, uncontrolled selection
Consultation type 6	Citizen panel – e.g., health panel	Ongoing debate of topics; controlled selection, open responses
Participation		Information to/from <-> public
Participation type 1	Planning workshop, citizens jury	Controlled selection, facilitated expert and other inputs, open responses
Participation type 2	Negotiated rule making; task force	Groups access pertinent information to solve problems; open responses controlled selection, inputs unfacilitated
Participation type 3	Deliberative polling or planning cell	Polled before/after deliberation; controlled selection, open responses
Participation type 4	Town meeting with voting	Voting after debate; uncontrolled selection; open response mode

All-Hazard, Risk-Based, Problem-Solving Approaches to Disaster Mitigation

The third example of this kind of social learning from earthquake events is taken from New Zealand and occurred in the aftermath of the 1987 M_w 6.3 Edgumbe earthquake. An earlier history of seismic activity, including the destructive M_w 7.8 Napier earthquake in 1931, had contributed to well-enforced New Zealand building codes. These codes, and the fact that the Edgumbe event occurred in a largely rural area, contributed to a lack of fatalities. These factors had not, however, been able to prevent total losses of NZ\$430 million. Drawing political and international attention to the potential for

much greater earthquake losses in New Zealand and the Pacific region, the Edgumbe event also highlighted the potential for losses associated with damage to critical facilities, including supply of water, electricity, and communications, as well as sewerage disposal and transport (Shephard 1997).

Largely in response to this event, major national policy changes “designed to encourage more effective safety and loss prevention strategies” were enacted in a series of subsequent government reforms, including the 1987 Recovery Plan for Natural Disasters, and reforms to the Local Government Act 1989, the Resource Management Act 1991 and the Building Act 1991

(Shephard 1997). The “essential idea” of these reforms: “was that central government would accept shared responsibility for the restoration of damage from natural disasters *only if the local authority concerned had done its part to minimize, mitigate and manage the risk to its assets...* they were expected to... *put in place protection and damage limitation measures that would reduce the consequences.*” (Helm 1996; cited in CAE 1997, emphasis added).

Where the focusing effect of US earthquake and oil spill disaster events had led to *hazard-specific policy reforms*, the New Zealand government emphasis on risk and decentralized responsibility effectively meant that the lesson learned from the Edgecumbe earthquake was to *prepare locally for all hazards*.

This political climate facilitated the collaborative Christchurch Engineering Lifelines Project, conducted in 1993 and 1994 by task groups that included physical scientists, academic and professional engineers, local and national government agencies, and representatives from relevant private sectors, including insurance and utility providers. The project was run out of the University of Canterbury’s Center for Advanced Engineering (CAE), which was founded in May 1987, 2 months after the Edgecumbe earthquake. The Christchurch Engineering Lifelines Project aimed to identify the vulnerability of critical facilities to damage from a *range of natural hazards* and to arrive at practical strategies to mitigate potential damage; it also aimed to communicate relevant issues to the people involved in managing the services and the public (CAE 1997). Creating detailed hazard and critical facility maps, multi-sector task groups came together to superimpose these maps, going over critical facilities in detail, network by network, to assess the likely vulnerability and importance of elements, discuss often inexpensive mitigation measures, and assess risks associated with network interdependence.

Rather than simply translating scientific findings into risk reduction policy and practice, this project involved the collective, cogeneration of risk reduction knowledge through the interactions of scientists, engineers, local government,

and those with day-to-day experience of the relevant lifelines. In addition to being deeply local and enabled by a strong national policy framework, this project was also informed by globally networked international research and industry communities.

The initial assessment phase was conducted during 1993 and 1994. In collaboration with the New Zealand Society for Earthquake Engineering (NZSEE) and with financial support from New Zealand’s Earthquake Commission (EQC), project members also visited Los Angeles in 1994 following the M_w 7.2 Northridge earthquake and Kobe after the 1995 Great Hanshin earthquake. The Christchurch project was detailed and disseminated in a 1997 report (CAE 1997). In addition to summarizing the mitigation measures already carried out and ongoing project work, this report noted that “a very significant benefit” had been the formation of the multilateral working group, which had brought together those with “dissimilar working interests,” and so established useful ongoing relationships “in preparation, as it were, for a major emergency requiring the various utilities to work together” (CAE 1997). The subsequent Civil Defence and Emergency Management Act (2002) built on this legacy. Devolving hazard and emergency management to the local level and supporting the integration of regional lifelines groups in emergency management training programs, this act reinforced the culture of hazard mitigation, contributing to a community of practice involving regional providers of critical facilities.

In 2010 the M_w 7.2 Greendale earthquake began the destructive “Canterbury earthquake sequence” that included the M_w 6.2 Christchurch earthquake on 22 February 2011. Leading to 185 deaths in Christchurch, widespread liquefaction and lateral spreading in the central and eastern suburbs of the city, this event caused extensive damage to buildings and critical facilities. In a recent study, the Lifelines project and its outcomes have been estimated to have significantly reduced the impacts of the earthquake sequence on the city (Fenwick 2012).

Risk reduction initiatives developed through the project are estimated to have greatly reduced

the overall community losses associated with critical facility outages. Investment in alternative, redundant supply routes for electricity and telecommunications allowed for rapid restoration of supply in all but the most badly damaged regions. Telecommunications companies with “strong node” and alternative “hot spot” buildings were able to maintain coverage in the city. Seismic strengthening in the city’s port, directly over the epicenter of the damaging 22 February 2011 event, made it possible for a New Zealand naval frigate to dock and unload aid and supplies within 4 h of this event; the port was operational again within days (Fenwick 2012).

Utility companies that had adopted a consistent focus on risk mitigation also saved significantly in direct asset replacement and repair costs. Electricity provider Orion Energy, for example, spent \$NZ6 million on seismic strengthening and is estimated to have saved \$NZ60–65 million, while the total repair costs after the February event paid by another provider, Transpower, amounted to only \$NZ150,000 (Fenwick 2012). By contrast, much of the aging water and wastewater network the project had identified as a seismic risk had proved too expensive and difficult to upgrade. The 2014 estimate of the cost of repairing these seismically damaged networks is NZ\$2 billion (SCIRT 2014).

At least as valuable as the financial saving was the networked community of professional and academic engineers, infrastructure companies, and local and national authorities created by the project and further developed by EQC, NZSEE, and MCDEM initiatives. This collaborative critical facilities culture greatly facilitated the restoration of lifeline function after each of the four major events in the 2010–2011 Christchurch earthquake sequence. It has also informed the “Stronger Christchurch Infrastructure Rebuild Team” (SCIRT), a formal alliance of national and local government agencies and private organizations tasked with rebuilding the city’s horizontal infrastructure (SCIRT 2014). Designed to “harness the expertise of public and private sectors, promote information sharing and

Learning from Earthquake Disasters, Table 2 Comparative policy learning from earthquake disasters in the United States and New Zealand

<i>In the United States and New Zealand:</i>	
<i>Major earthquakes caused extensive damage</i>	
At a time when governance structures were extending to include non-state actors	
Creating a widespread perception that existing legislation had failed	
Leading to a range of legislation designed to address issues exposed by the event(s)	
Generating increased research activity

<i>Differences:</i>	
United States	New Zealand
Hazard-specific legislation	All-hazard legislative focus
Hazard-specific research and coalitions	All-hazard research and coalitions
Higher-level initiatives and organizational coalitions	Devolution risk management to local-level initiatives and organizational coalitions

collaboration, and manage risks and opportunities” this work program includes seismic strengthening (SCIRT 2014).

As in the US examples, it is clear that the 1987 Edgecumbe earthquake occurred at a time in which governance structures were being extended; the earthquake thus contributed to a widespread consensus that policy change was required, a range of legislation devolving responsibility for risk reduction to the local level, increased research activity, and the motivation to form the ongoing coalitions holding the relevant learning network together. The 2010–2011 Canterbury earthquake sequence confirmed the value of this learning, while also focusing attention again on the need for seismic risk reduction and so informing the Stronger Christchurch Infrastructure Rebuild Team initiative.

However, the multi-hazard approach and the devolution of responsibility for all hazards to the local level differ significantly from the *hazard-specific* US policy responses to earthquake disasters (see Table 2).

To the extent that it has required that local authorities, communities, researchers, and the private sector work together to reduce the risks of a wide range of hazards in their own local region, the focusing effect of an earthquake disaster has been used to reduce the risks associated with a much wider range of disaster types. This can be seen as an example, then, of the kind of “all-hazard, risk-based, problem-solving approach” to disaster risk reduction recommended by UNISDR, which requires “collaboration and communication across the scientific disciplines and with all stakeholders, including representatives of governmental institutions, scientific and technical specialists and members of the communities at risk to guide scientific research, set research agendas, [and] bridge the various gaps between risks and between stakeholders” (UNISDR 2014). On the other hand, however, this process remained limited in focus to the vulnerability of city infrastructure – it did not include social vulnerability or involve the significant public participation constituted by the RCAC; so to this extent, it did not involve the collaboration with “all stakeholders” specified by the UNISDR.

Challenges to Learning from Earthquake Disasters

Considering the challenges to this kind of learning after earthquakes means turning from work focused on the opportunities offered by the focusing effects of earthquake events, increasingly networked global communities, and the extension of governance to include social actors to work that is focused on the *risks* posed by the same developments. This section starts with challenges to the formation and operation of collaborative, “innovative” learning or policy communities, and a brief discussion of identified barriers to higher-level responses to earthquake disasters. Data management issues and wider implications of the role of focusing disaster events and unsustainable global development conclude the section.

Challenges to Multidisciplinary, Multi-sector Learning After Earthquakes

The processes that bring actors together from across sectors and disciplines to coalesce around the shared goal of risk reduction are also at work around the sets of ideas or paradigms that are shared within individual disciplines, organizations, and sectors. At every level, incompatibility between these idea sets, or shared norms and values, have been found to have the potential to inhibit knowledge sharing and so impede the translation of scientific knowledge into policy and practice.

This is apparent in Birkland’s (1998) comparative study, for example, which revealed that a relative lack of focusing effect effectively left the hurricane policy domain dominated by local government interests, who prioritized policies that were *relevant to their constituents*. This meant they preferred engineered solutions like levees nonstructural mitigation techniques, such as stricter enforcement of flood plain regulation or coastal development, considered by Birkland and other researchers to be a more *scientifically credible* mitigation approach. Similarly, the “ambiguity” of the harms caused by nuclear accidents had left *commercial* industrial interests dominating the nuclear disaster policy domain. Focusing events had been required in the oil spill and earthquake domains to generate enough social and political pressure to trigger higher-level commitment to risk-reducing policy change. Without this shift in the political environment, the natural disaster domain remained dominated by the drive for *political relevance*, while the industrial disaster domain remained dominated by the commercial drive for *financial profit*; neither of these drivers was compatible with the drive for *scientific credibility* of concern to Birkland and Busenberg.

Incompatibility between these drivers has also been found to significantly inhibit the translation of scientific findings into policy and practice at the level of individual decision-making. In a recent study, for example, policy makers and practitioners working in disaster risk reduction and environmental management domains, in

both developed and developing countries, did not access relevant academic publications unless they had been directly involved in their production (Weichselgartner and Kasperson 2010). They were in any case reluctant to use this research – assessing the vulnerability and resilience of populations in their own geographic jurisdictions – to inform decisions about disaster risk reduction and environmental policy and practice. Although conceding broad relevance, policy makers and practitioners did not consider these research findings to be relevant to their specific knowledge needs (Weichselgartner and Kasperson 2010). At the same time, even in this domain, where researchers are typically highly motivated to contribute to disaster risk mitigation, the authors of the relevant publications acknowledged that their work was largely driven by considerations of *scientific credibility* and so designed, conducted, and disseminated with an academic audience in mind, rather than the needs of potential users (Weichselgartner and Kasperson 2010).

By creating incompatible cultures and values, these drivers have also been found to contribute to value clashes between academic and other spheres that inhibit cross-sector collaborative activity (Cash et al. 2003). Academic incentive regimes are based on publications and peer recognition, which have been described as academic “status competitions,” sometimes taking “the form of winner takes all” when it comes to publishing first or winning research grants (Bruneel et al. 2010). Contesting the credibility of findings is an essential part of the peer review process, informing a value set in which contest is more usual than that in private and government sectors, where individuals are required to subordinate their own interests to those of their organization and where commercial and political incentive regimes can require that knowledge is kept private, rather than contested in the public domain (Bruneel et al. 2010).

In a range of collaborations involving research and private sectors, these differences in cultures, norms, and values have been found to inhibit collaborative knowledge production. Conversely, ongoing cross-sector engagement over time has

been found to *significantly reduce* this inhibiting effect (Bruneel et al. 2010; Cash et al. 2003). The balance of contestation and consensus building required to initiate and continue such cross-sector engagements, however, has been found to be delicate; major value clashes have been found to be particularly compromising.

Challenges to Higher-Level Learning from Earthquake Disasters

The tensions between potentially incompatible scientific, economic, and political drivers that have worked against coordinated disaster risk reduction initiatives at local and national levels are also in evidence in the recent global developments that have reduced political authority at these levels. Economic integration and market liberalism have limited the political authority of governments over multinational economic actors; bodies like the WTO are able to impose global political requirements on nation states that often conflict with the demands of their constituents, and information and communication technologies have facilitated both global economic transactions and transnational networks of civil society actors (Skogstad 2003). These limitations on political authority at the national level, moreover, have not been evenly distributed. Less affluent, developing nations have been much less well positioned than developed nations when it comes to asserting political sovereignty over the activities of multinational companies and against the political strictures of global organizations. Consequently the nations *most exposed* to disaster risk have also been those nations least able to shoulder the responsibility for disaster risk reduction that continues to fall to national government level.

This has meant that developed countries that experience earthquake disasters are more likely to benefit from the distribution of political, public, and international attention and have more to gain from the resultant focusing effect than developing countries. A sequence of Global Network reports has found that networked disaster risk reduction activities involving “state and non-state actors” working “together to ensure the safety and well-being of their communities”

have been much more effective “in countries where capable, accountable and responsive local governments worked collaboratively with civil society and at-risk communities” (Global Network 2013). However, there has been very little progress in developing countries across a range of risk governance indicators, including “lack of political authority; inadequate capacities and financial resources; and minimal support from central government,” which have all been identified as “significant barriers” to the implementation of disaster risk reduction policies at the local level (Global Network 2013).

In many countries, this can mean that rather than triggering risk-reducing policy changes, the focusing effect of a major earthquake disaster can instead generate a tidal wave of international aid and more or less fragmented and competitive activity among aid organizations. Dombrowsky, for example, has found US\$4 billion in aid donated worldwide after the 2004 Sumatran earthquake and subsequent tsunami provided an “excessive” volume of food and clothing that “wrecked local agricultural, market and production systems,” while the “accelerated” building of new housing created “extreme shortages of materials, harmful deforestation, profiteering and, more recently, inappropriate construction methods” (Dombrowsky 2007). The “tens of thousands of projects” carried out by competing international organizations in Southeast Asia after the Sumatran earthquake and tsunami “were not networked and there was no co-ordination aimed at developing a long-term, preventive protection and sustainability strategy” (Dombrowsky 2007).

Conversely, Christoplos (2006) has argued that although scientifically credible, disaster risk reduction initiatives can be incompatible with local and global *political* imperatives after disasters. Informing the humanitarian focus on “addressing acute human suffering,” these political drivers also inform the immediate priorities for local “politicians, donors and disaster affected people,” who need to get “people out of tents and into houses and off food aid and into jobs” (Christoplos 2006). In addition, he noted that the 2004 tsunami decimated many of the local

governments and communities required to develop networked community disaster risk reduction initiatives. He has called for compromise, rather than blame casting and identifying “villains,” from those working toward disaster risk reduction, in order to achieve a consensus concerning larger, shared goals (Christoplos 2006).

Data Management Challenges to Learning from Earthquake Disasters

The focusing effect of disasters has also been found to contribute to the enormous volume of post-disaster reviews, investigations, and evaluations, most entitled “lessons learned,” which are conducted and documented at different levels, in a range of government, academic, NGO, and private sectors. Again, this material is largely produced in response to *political* pressures and so conducted to reassure relevant authorities and the public that an attempt to learn lessons has been made, rather than to generate scientifically credible evidence for policy change (Birkland 2009). International aid agencies are also under intense political pressure to prove that their money is being well spent. This pressure can lead NGOs to compete for prestige projects and the associated positive publicity. It also contributes to considerable information gathering, largely for internal consumption, within organizations (Dombrowsky 2007). Much of this material may contain risk reduction lessons of scientific and practical value. It cannot, however, be easily accessed, since it is not coordinated or collated, but remains fragmented, dispersed within agencies and organizations, and across a diverse range of academic journals (Birkland 2009).

The same issue occurs at the global scale. As the pace with which information technology evolves outstrips the capacity to *coordinate* data management across local, national, and global levels, it becomes increasingly difficult to establish global disaster data. Organizations like Munich Re and the Center for Research on the Epidemiology of Disasters (CRED) have been set up to address this issue by gathering credible, comparable global data and providing it in an

accessible form. Even these organizations, however, are struggling with inconsistencies created by “the use of different data sources, different frameworks, different metrics, or different scales” and because of “a lack of consistency in the management of the data on which the assessments are based” (ICSU 2009).

The management and accessibility of *research data* in this area has also been identified as an urgent issue. The 2013 OECD Global Science Forum report on Data and Research Infrastructure for the Social Sciences, for example, addressed “rapid growth in new forms of data collected in conjunction with commercial transactions, internet searches, social networking, and the like, and by technological advances in the capacity to access and link existing survey, census, and administrative data sets.” It was tasked with weighing the opportunities offered by this growth for evidence-based research concerning disasters and other global challenges related to the health and well-being of populations around the world (OECD 2013). Issues identified in this report as imperative included the difficulty of accessing the large volumes of data collected and held by the government and private sectors; ethical issues associated with the use and sharing of data concerning human subjects; the need to standardize, manage, and archive data in accessible formats; and the urgent need for more international comparability and collaboration. All these issues reflected a larger problem: the need for a more integrated, coordinated approach to the collection, management, and archiving of data, at every level. The report concluded that the “the need for global coordination of activities designed to address the challenges identified in this report is paramount” (OECD 2013).

This has been identified as the paradox of the twenty-first century (Dombrowsky 2007). More data is available than ever before, in a huge range of areas. Existing national structures and systems, however, are no longer able to manage the complexity and volume of multinational data flows, and there are as yet no global structures and guidelines through which such data can be managed, coordinated, and applied for disaster risk reduction purposes.

Challenges to Learning from Disasters Arising from Focusing Effects

The lack of coordinating structures at the global level is also an issue when it comes to coordinating disaster risk reduction efforts. Incompatible economic, political, and scientific drivers have been found to be best coordinated, at the national level, through policy frameworks that facilitate an integrated focus on the issue of disaster risk reduction. At the global level, however, where similar pressures are contributing to rising disaster losses, there are as yet no structures with the authority or means to establish equivalent global frameworks.

Disaster sociologists point to the extent to which the social issues created by global tensions, rather than being foregrounded by rising disaster rates, have instead been *obscured* by the focusing effect of major natural disasters like earthquakes and tsunami. By drawing attention to the drama associated with such natural forces, in other words, earthquakes and other natural disasters have distracted attention from the extent to which the capacity to cope with and recover from such extreme events can be reduced by lack of resources, including access to information, financial credit, social support, and services. The focus on major natural disasters can thus obscure the fact that populations constrained in this way are more vulnerable to death, injury, and loss during disasters and less able to recover (Gaillard 2010).

On the larger scale, the focusing effect of dramatic earthquake disasters is understood to work in a similar way, grabbing attention from the impacts of climate-related disasters, which are particularly common in less developed global regions. Climate-related events have the most destructive global impact; cause the greatest losses, the most deaths; and are also the hazard event category that is increasing in frequency (Global Network 2013). Moreover, this class of disaster includes the less dramatic, ongoing “everyday disasters” such as droughts and floods, which are collectively responsible for more disaster losses than the more dramatic major events. The hazards associated with extreme poverty have also been found to fall into the category of

“everyday disaster” – responsible for the vast majority of harms and deaths affecting the global human population, but obscured by the focus on so-called “natural” disasters (Global Network 2013).

These issues have had a fragmenting effect within the scientific community. It has been argued, for example, that hazard and vulnerability disaster risk reduction traditions are informed by inverse and fundamentally incompatible paradigms. Such arguments have contrasted a hazard mitigation emphasis on infrequent, major natural disasters, and reliance on expensive technical solutions, designed and implemented at high levels by expert groups and delivered through top-down mechanisms, with the emphasis of vulnerability-based approaches on the social causes of disasters, and on bottom-up, participatory approaches designed to counteract these social constraints (Gaillard 2010). Related constructivist critiques have emphasized the risks to democratic process associated with the delegation of policy formation to subgovernment networks and have been similarly critical of disaster risk reduction policy and initiatives developed by experts that fund technical risk reduction measures, rather than public engagement mechanisms, and measures to address the social issues that contribute to disaster impacts (Hayward 2013).

Summary

There is general agreement within research and policy communities when it comes to some broad principles concerning learning from disasters. Governments are responsible for putting policy frameworks in place to support risk reduction initiatives. Implemented at both national and local levels, the most effective initiatives have reduced fragmentation and competition by adopting collaborative, cross-sector participatory approaches in an attempt to include as many stakeholders as possible, including those most exposed to disaster. Earthquake disasters have had a focusing effect on policy agendas in the US. Higher-level support, policy frameworks that

facilitate risk reduction, increasingly networked global communities, and multilateral learning networks have been found to be key factors in the translation of science into disaster risk reduction policy after major events. In New Zealand, learning from earthquake disasters has informed an all-hazards risk reduction approach and a policy framework that has devolved responsibility for risk reduction to local levels. There is broad agreement that this kind of current extension of the government sphere to include both state and non-state actors in policy formation and implementation can facilitate such approaches and can also facilitate the translation of science into policy and practice, when researchers take the opportunity to engage with all end-users, at both national and local levels.

White et al. have argued that this kind of consensus reflects an increasing convergence in the hazard and disaster research community around the common goal of disaster risk reduction, notwithstanding cross-disciplinary tensions concerning disaster risk reduction priorities and the risks and opportunities associated with the extension of the government sphere. This convergence is also indicated in a cross-disciplinary agreement concerning the importance of working through such tensions collaboratively, both within the scientific community and with other sectors involved in disaster risk reduction.

Fragmentation, competition, and lack of coordination, however, have been found to inhibit the development of multilateral disaster risk reduction initiatives at local, national, and global levels and within and across disciplines, sectors, and domains. At both local and national levels, *coordinating measures* introduced after disasters have been found to reduce fragmentation and balance competition, both within and between sectors. Such measures have facilitated the compromises between economic, political, and scientific drivers required by collaborative risk reduction initiatives. Global disaster risk reduction is challenged by the absence of similarly authoritative coordinating mechanisms at this level and related issues arising from the rapid and uncoordinated development of information technology, the distribution of vulnerability to disasters, the

emergence of subgovernment policy communities, and aspects of current emphasis on risk and disasters. Unsustainable global development, widely acknowledged to be a causal factor in rising disaster losses, also continues to significantly inhibit disaster risk reduction at both national and local levels and so the wider global disaster risk reduction effort.

tends to slow recovery, but often they facilitate in building a better, more resilient, post-disaster environment. In this entry, the focus will be on the common post-disaster legislative changes encountered for reconstruction, such as those affecting building acts and building codes. Examples and effects of the changes are discussed using a variety of cases from earthquakes and other disasters. This entry provides an account of the ways in which legislation changes post-disaster can help and/or hinder reconstruction programs.

Legislation Changes Following Earthquake Disasters

Disaster legislation; Legislation changes post-disaster

Introduction

Most disasters are followed by legislative changes, emergency legislation, and new disaster legislative measures. Some of the changes are a reaction to the need to build back safer and to be seen to be facilitating a better future environment. For instance, the Royal Commission into the Canterbury Earthquakes in New Zealand recommended changes to the Building Act, a rewrite of building codes and building standards. Other disasters, such as the Wenchuan earthquake in China, Black Saturday bushfires in Australia, and Hurricane Katrina and Northridge earthquake both in the USA, had all occasioned changes in legislative requirements for reconstruction and code changes for buildings. The impact of legislative changes

Legislation Challenges Post-disaster

The organization and coordination of recovery is usually complex because a wide range of activities occur simultaneously after a significant disaster. There is an equally wide range of needs that would have to be met, some of which may be conflicting and adds to the complexity of post-disaster recovery. Experiences from past disaster recovery arrangements show a struggle to meet recovery needs and changes to the legislative, and regulatory recovery environments seem common place. Several contributory factors account for the success or otherwise of disaster management goals and objectives, irrespective of whether they are in legislation or in recovery management plans. These include:

- Pre-disaster trends and levels of preparedness which are linked to vulnerability
- The extent of damage resulting from the disaster
- Availability and accessibility to the required resources for both response and recovery
- The prevailing political will and governmental interests in disaster management activities

In terms of legislation and regulation, there is often little provision in legislation to facilitate large-scale reconstruction programs. Prior to the Canterbury Earthquakes in New Zealand, Feast (1995) had identified several issues in relation to planning and construction legislation that could impede reconstruction of Wellington, following a major earthquake. Feast's study suggested that

much of the legislation (in particular the Resource Management Act (RMA) and the Building Act (BA) that existed during the period was neither drafted to cope with an emergency situation nor developed to operate under the conditions that would prevail in the aftermath of a severe seismic event. Specifically commenting on the RMA, Feast had explained that its consultation procedure could prevent meeting the reconstruction requirements of a devastated city within a reasonable time period (Feast 1995). Decades after in 2012 (following the Canterbury earthquakes), some of Feast's suggestions were relived, and changes to both the RMA and BA were, and are, still being made based on recommendations by the Royal Commission set up to review the Canterbury recovery program. Changes around seismic codes, strengthening of existing buildings, changes to land use, and planning parameters are being made as a response to the Canterbury disaster.

Rolfe and Britton (1995) are of the opinion that the pace of reconstruction is severely impacted by political and cultural conflicts over recovery plans, which means the successful achievement of disaster management goals will depend on the political environment. Once a disaster happens, there is a continuous tension between strictly applying reconstruction regulations which aim at preventing a recurrence of the previous community vulnerabilities and allowing an affected community to move back to their former habitation quickly. Clearly, the quicker communities return to habitability of as many of their homes as possible, the better it will be for restoring a sense of normality. However, to reduce future vulnerabilities, it is rational to approach rebuilding programs cautiously to build in resilience and build back better than before the disaster. In New Zealand, the rebuilding of Napier following the 1931 earthquake did not reduce vulnerabilities to future disasters as the city was rebuilt in the same location mainly producing unreinforced masonry buildings. Retrofitting of Napier buildings was subsequently required under new seismic codes because, as has been repeatedly demonstrated, unreinforced masonry buildings are vulnerable to earthquakes.

When considering the effects of legislation changes after disasters, it can be seen that legislation changes post-disaster can be broadly classified into two categories: (1) legislation for compliance and (2) legislation for facilitation. *Legislation for compliance* entails using legislation to enforce recovery initiatives, such as those that would require buildings to be upgraded or rebuilt to different standards and codes. The lack of enforcement of hazard-related laws and adequate risk-based building controls contributed to the large-scale devastation caused by the 2004 Indian Ocean tsunami (Mulligan and Shaw 2007). The same was witnessed in countries such as Pakistan, Turkey, Samoa, and Haiti. In reconstruction programs, there is a need to enforce the new building design codes which inevitably appear after a disaster. Inspection of the reconstruction, including buildings using the new codes, requires clear guidelines to maintain the required standards.

Legislation for Facilitation denotes legislation being used to simplify and assist recovery activities to speed up the recovery process. These changes can usually be seen in changed processes, such as in building and development consent processing. However, legislation that is customarily used to impose security and safety controls (such as building consents) can become an obstacle to rebuilding programs. Time-consuming procedures, insufficient resources to process permits, and lack of fast-tracked methods could delay reconstruction. For example, delays in the issuance of permits were a major reason for the holdup in housing repair and rebuilding following the 2005 Bay of Plenty storm in New Zealand (Middleton 2008). Fast-tracked consenting procedures, collaboration between councils, open access to information between stakeholders, and using legislation to remove bureaucracy are viable options to speed up recovery. During the 1994 Northridge earthquake, legislation was suspended, and emergency powers were used with the consequence of reducing highway reconstruction time. Similarly, during recovery from the Australian bushfires, planning and building permits were exempted for temporary accommodation so they could be put up

quickly. For permanent dwellings, planning permits were exempted, and only building permits were needed after the bushfire (DPCD 2013). Also property falling under the Wildlife Management Overlay which would normally be subject to more rigorous planning and building permit requirements had to be relaxed to only require a simplified planning consent and building permit (DPCD 2013).

From the forgoing, it is clear that legislation and regulatory requirements can have significant influence on the rate of recovery after a disaster event. The overall desire is for legislation to enhance the recovery and reconstruction process so that it improves the functioning of an affected community and reduces risks from future events. Any legislation changes that need to be made post-disaster may be better considered before a disaster so that its implementation could be facilitated early on during recovery. Often the opportunities to introduce mitigating measures become limited over the course of recovery because of the desire to return to normalcy and thus rebuild quickly after disasters. Menoni (2001) notes that “market forces put pressures to reconstruct as quickly as possible . . . hampering efforts to implement lessons learnt from the disaster in the attempt to reduce pre-earthquake vulnerability.”

Pressures to rebuild critical infrastructure quickly are borne by national and local administration with the possible implication of reduced quality of delivery. Rushed rebuilding programs have led to increased vulnerability of poorly planned and designed built environments to future disasters (Jigyasu 2010). Ingram et al. (2006) also explain that the clamor to rebuild quickly amplifies the underlying social, economic, and environmental weaknesses that result in large-scale disasters (Ingram et al. 2006).

Improving Recovery Through Legislation

Well-articulated and implemented legislation should not only provide an effective means of reducing and containing vulnerabilities (disaster

mitigation) but also become a means of facilitating better thought out and designed reconstruction programs.

After damage assessments and evaluations, building and environmental legislation should not present impediments to reconstruction and rebuilding programs. Martín (2005) suggests that there is a relationship between building/environmental regulations and rehabilitation works (Martín 2005) and that regulations could become burdensome in rehabilitation and reconstruction projects and are worthy of considerations (Martín 2005). Martín (2005) describes burdensome regulations as those which incorporate excessive rules and regulations and red tapes (statutory procedures) that add unnecessarily to costs. Listokin and Hattis (2004) provide useful analysis on two kinds of barriers that building codes could pose to rehabilitation works. They are “hard” and “soft” barriers to rehabilitation. The hard barriers are impediments to rehabilitation as a result of overregulation, which would not add appreciably to building value or public safety (Burby et al. 2006) and could discourage housing development or rehabilitation because they are added burdens (May 2004). For instance, building and environmental regulations that do not reduce the vulnerability of built assets to a hazard event are unnecessary. Also to insist on expensive structural solutions in a highly hazardous zone, where a simple alternative will be to restrict development in that zone, is another example of regulation that could fall under Listokin and Hattis’ hard category.

Soft impediments, on the other hand, are administrative requirements that require extra time, money, and effort to accomplish rehabilitation and reconstruction projects (Listokin and Hattis 2004). These are red tapes (bureaucratic procedures) that could delay new construction and rehabilitation/reconstruction of physical facilities (May 2004). Such soft impediments are the focus in this entry.

Bureaucratic procedures must be supportive of emergency management under different emergency scenarios whether routine or chaotic. However, research suggests that bureaucracies have been less supportive of the

expediency that is desired in disaster response and recovery. May (2004) suggests three sources of impediments by regulatory processes:

- Regulatory approvals. These are delays associated with consent processes and approvals that arise from cumbersome decision-making processes and duplication of regulations. These types of delays are inherent in building and environmental legislation.
- Regulatory enforcement strategies and practices. These are overly rigid practices that foster an unsupportive regulatory environment for the development and rehabilitation of the built stock. In post-disaster situations, rigid enforcement strategies discourage genuine recovery efforts.
- Patchwork of administrative arrangements. This could result from duplication of administrative structures (as in layers or hierarchies of control) and gaps in regulatory decision processes. May (2004) explains that patchwork frustrates regulatory implementation and adds to complexities in regulatory processes.

Regulatory process barriers could also result from *administrative conflicts* in and among disaster agencies (Listokin and Hattis 2004). For example, rivalry between responding agencies is not foreign to emergency services and is an obstacle to effective emergency management (McEntire 2002; Quarantelli 1998). Rotimi (2010) explains that rivalry may result from existing silos, from the absence of a coordinating agency, and from the ability of a coordinating agency incorporating other agencies perceived responsibilities. Hence, a broad cooperative effort is needed for the success of post-disaster reconstruction activities. Rotimi (2010) therefore contends that organizations have to coalesce to plan for resource utilization in the restoration of physical assets. Coordination is therefore central to multi-organizational response and recovery programs (McEntire 2002). This multi-organizational coordination is often embedded into emergency legislation post-disaster and usually involves the creation of new recovery coordinating agencies such as Victorian

Bushfire Reconstruction and Recovery Authority (VBRRA) in Australia or Canterbury Earthquake Recovery Authority (CERA) in New Zealand.

Another useful dimension to the problems with burdensome regulations is provided by Listokin and Hattis (2004). It is that regulatory procedures could become too rigid forcing implementers to “go by the book” even though variations may be warranted. This places implementers in a state of continuous fear of liability should things go wrong. Rotimi (2010) explains that some latitude of control and discretion is often required to aid decision-making as long as such decisions are pragmatic. Commenting on the rebuilding program after the flooding incident in New Orleans, Stackhouse (2006) says “removing democratic processes from the rebuilding process has the advantage of expediting decision making by allowing politically dangerous but practical outcomes.” This statement suggests that greater freedom in decision-making by officials of coordinating agencies could increase the speed of rebuilding programs after significant disaster events. Evidence from literature on recovery often shows slow recovery. For example, on the Bay of Plenty storm in New Zealand in 2005, Middleton (2008) showed that at 300 days after the event, 35 households still required permanent rehousing out of a total of 300 compulsory evacuations. At the same time, nine households were still occupying temporary accommodation. Middleton (2008) suggests that the slow pace of recovery was attributable to the inadequacy of personnel to carry out the stipulated building safety evaluations and to process consents for reconstruction work. Both of these factors have legislative connotations.

Considering New Zealand before the Canterbury earthquakes, there was an emphasis on readiness and response activities, with little consideration given to planning for sustained recovery activities. Where recovery was considered, it was for the short term, as evident in emergency awareness campaigns that encouraged communities to prepare for 3–7 days after an event. Recent emergency events clearly show that longer-term recovery plans and more robust legislation were required given the complexities

associated with the rebuilding of damaged built assets. Warnings about the inadequacies of routine construction processes being modified on an ad hoc basis during the small disaster recovery phases in previous hazard events were unheeded in New Zealand (Rotimi et al. 2006). While such an approach works reasonably well for small-scale emergencies, the effectiveness of reconstruction in a large disaster required large-scale legislative changes (Rotimi et al. 2009). Post-Canterbury, an extensive review of legislation to cope with future disasters is now underway.

Post-disaster Legislation Changes in Action: Three Case Studies

Despite the type of disaster, there are often commonalities in the post-disaster legislative changes enacted and the impacts of these changes. Starting with an earthquake, and ending with a fire, this section demonstrates through three cases, the impact of legislation on recovery and some good and bad practices.

The Northridge Earthquake, USA, 1994

The Northridge earthquake provides an example of a disaster situation where legislative changes helped to facilitate reconstruction projects. The moderate earthquake struck Southern California in the early hours of 17 January 1994 with a magnitude of 6.8 on the Richter scale, small compared to other earthquakes, but causing significant damage.

Comerio (1996) gave an insight into the extent of damage. There were damage to 27 bridges and a collapse of sections of six freeways. Four hundred and fifty public buildings suffered significant damage, 6,000 commercial buildings, 49,000 housing units in 10,200 buildings had serious structural damages, while 388,000 housing units in 85,000 buildings experienced minor damages. The total value of damage to houses in Los Angeles was estimated to be about \$1.5 billion.

The Northridge earthquake caused a shift in emphasis from disaster preparation and relief to

recovery (Comerio 1996), and this shift largely resulted in the success of emergency management programs for the restoration of the affected areas. Reconstruction contributed to the economic revitalization of the affected area, and bureaucratic requirements were suspended to encourage rapid rebuilding of damaged infrastructure. Marano and Fraser (2006) conclude that “identifying and easing regulations and statutes that inhibit reconstruction can mean a dramatically faster and less costly recovery.”

Wu and Lindell (2004) provide an insight into some of the actions that were taken to increase the speed of housing reconstruction in Los Angeles after the earthquake showing that it is possible to expedite procedural requirements by establishing fast-tracked processes that would operate after a disaster would benefit recovery.

While the rapid recovery experienced after the Northridge earthquake can be attributed to other factors, such as political will, public policy changes and enabling emergency management legislation played a substantial role in the rebuilding programs after the earthquake (Comerio 2004).

Hurricane Katrina, New Orleans, USA, 2005

The disaster that followed Hurricane Katrina provides lessons on legislative changes either proposed or already implemented to enable its recovery from the event. The Hurricane was a category 3 storm when it struck New Orleans and the Gulf Coast in the morning of August 29, 2005. The storm surge caused severe destruction along the Gulf Coast from central Florida to Texas in the USA. The most severe damage occurred in New Orleans, Louisiana, because of the failure of the levee system that was designed to contain the resulting storm surges. The worst damage was caused by floods with an estimated 1.2 million people evacuated before the incident and another 100–120 thousand afterward. About 350,000 houses were destroyed and over 200,000 persons required temporary shelters scattered around 16 states in the USA. By all accounts, Hurricane Katrina was a catastrophic event with economic loss estimates of about \$200 billion (Burby et al. 2006).

A brief description of some of the policy changes and legislative reviews that occurred as a result of Katrina is provided by Rotimi (2010) including:

1. Changes in building codes and standards. There were changes made to the building codes in New Orleans with a view in improving the resilience of built spaces in New Orleans. For example, there were revisions made to the base flood elevation levels for new construction to 3 ft or higher (Colton et al. 2008). This is a risk mitigation strategy which has been tied to flood insurance cover so that only buildings that meet these new guidelines can qualify for flood insurance and subsequent compensations. Overall, funding sources and budget priorities have been developed for reconstructing flood protection in New Orleans (Colton et al. 2008).
2. Changes in emergency management regulations and guidelines. Colten et al. (2008) explain that the Katrina event necessitated the review and updating of Louisiana and New Orleans' response strategies and their emergency operations plans. The legislative reviews included the adoption of an all-hazards approach thus expanding the scope and magnitude of anticipated hazards and allowing greater involvement of non-agency actors who proved crucial to response and recovery after the event. Colton et al. (2008) noted that partnering with nongovernmental stakeholders was a paradigm shift that emerged out of the Katrina experience.
3. Changes in land development regulations. Changes to land and development regulations are largely seen as a veritable tool for mitigating disaster risk in disaster management (Ingram et al. 2006). After Hurricane Katrina, changes in land use planning and zoning systems have been proposed to reduce the vulnerability of the New Orleans region from future flooding disasters (Burby et al. 2006).

The legislative changes in New Orleans show the importance placed on built asset

reinstatements as a major input to holistic recovery. Similar to Northridge, building reconstruction in New Orleans aimed to stimulate development and growth. The rate at which recovery is achieved is therefore tied to the speed of reconstruction, and any recovery is underpinned by well-thought-out and implemented legislative and regulatory changes.

Victorian Bushfires, Australia, 2009

The "Black Saturday" disaster was one of the most damaging disasters in Australian history, leaving 173 people dead and many seriously injured, affecting 6,000 households, destroying more than 2,000 homes, and damaging around 430,000 ha of land. Despite the institutions and procedures set up for expediting community recovery, reconstruction proceeded slowly. Shortly after the bushfires in March 2009, the Victorian Government introduced a new residential bushfire construction building standard AS3959-2009 in response to the need to better protect the bushfire-affected communities from future fire events. Under the new codes, there are increased construction requirements depending where a building is situated, ranging from ember protection to direct flame contact protection.

Changes have been documented by Mannakkara and Wilkinson (2013) which showed that one of the first steps taken in Australia was to publish a revised edition of the Australian building code for bushfire-prone areas (AS 3959) on March 11, 2009 (VBBRA 2009). The revisions introduced Bushfire Attack Levels (BAL) to identify the bushfire risk of properties. Stringent design and construction requirements were specified for each BAL to provide greater fire protection. Another key change in legislation was regarding land use. Soon after the fires, the entire state of Victoria was declared bushfire prone and placed under the Wildfire Management Overlay (WMO) which imposed stricter planning regulations (VBBRA 2009). The introduction of the buy-back scheme posed a solution for people on high-risk lands (Victorian Government 2012).

As with earthquake recovery, constructing bushfire-resistant buildings contributes to saving

lives and properties in the event of a bushfire. Mannakkara and Wilkinson (2013) report on the bushfire legislative and code change impacts. The more stringent construction requirements stipulated in the new Australian building standards are mainly concerned with the use of noncombustible materials for housing reconstruction. Bushfire housing reconstruction proceeded slowly because the advanced resources for direct flame contact protection such as the window systems, roof systems, shutters, and external cladding materials as required in the new AS3959-2009 were not available in the market. The main reason for the unavailability of these resources was that it required a considerable amount of time for manufacturers to undertake the research and development needed to test and release these new materials onto the market. Only in March 2010, a year after the bushfires, for instance, a combined window and screen system manufactured for use in direct flame contact protection zones was ready for release onto the market. The delays with production of compliant materials for the bushfire recovery, combined with growing demand on building services in the local construction market, created a series of scarcities, which greatly hindered housing recovery in the fire-affected areas. During the bushfire recovery, there were extra costs for the construction requirements of bushfire houses; these extra costs were significantly underrepresented (i.e., officially given assessments were from AUD 10,000 to 40,000 depending on the protection levels required, whereas the extra real cost of a house to be rebuilt to new codes was somewhere up to AUD 100,000). The increase in costs caused financial pressure for the affected house owners who already struggled to procure suitable resources for rebuilding their houses. The uncertainty about the number of houses in the direct flame contact protection zone was another major concern for the building product manufacturers.

Given few incentives from the government and the low likelihood of profitability, material producers were reluctant to put effort into developing materials for houses in the direct flame zone, which they believed would account for

only a small fraction of their market. Lack of training and understanding of the new standards introduced in Australia slowed recovery; even one and a half years after the bushfires, designers and builders were still trying to come to terms with the application of the standard.

General Implications of Legislation on Recovery

Having highlighted some of the issues that are connected to the appropriateness of legislation and regulatory provisions in the previous sections, this section presents a summary of their implication on recovery. The summary is in line with Rotimi (2010) who describes the effect that poor legislative provisions could have on post-disaster reconstruction activities, thus:

1. Loss of vital momentum of action. The efficiency of post-disaster reconstruction activities is impacted as a result of delays caused by poor planning and implementation, restrictive legislation and regulatory provisions, and lack of government commitment in reconstruction programs.
2. Loss of commitment to the reconstruction process. There is a tendency for poor commitment to recovery programs by responsible authority because disaster practitioners are unable to apply pragmatic solutions to real-time reconstruction problems for fear of being held liable for their decisions.
3. Difficulties in achieving reconstruction deliverables and inability to accelerate the process of reinstatement. Introduce measures for risk and vulnerability reduction and aid planning for sustainable developments.
4. Impairment of overall community recovery and quality of life. Of essence, reconstruction should become a tool for empowerment till a level of functioning is reached where communities are self-sustaining and require no external interventions and also a therapeutic process for overall community recovery.

Summary

This entry has shown common practices relating to changes in legislation for disaster recovery. Changing legislation after a disaster is a common response to the disasters but takes on different forms. Most disasters are followed by legislative changes, emergency legislation, and new disaster legislative, and these measures aim to encourage better building practices and future resilience. Putting in place legislation which enforces revised building codes to increase disaster resilience in the built environment is recommended as is that which speeds up slow processes or offers flexibility. Putting in place rigid rules and bureaucracies slows recovery and creates confusion. As cautioned by Ingram et al. (2006), legislative and regulatory changes need scrutiny to avoid issues such as resource constraints, high costs, and impacts on livelihood that can unnecessarily hinder recovery progress.

employed. In order to implement a successful remediation work for a target structure, a thorough understanding of the following are required: the liquefaction hazard at the site, the potential consequences of liquefaction for the structure, the performance requirements of the work, and the available construction materials and methods. Several alternative approaches can be taken if liquefaction poses as threat to existing or proposed structures. For existing structures, the choices are:

- (1) Retrofitting the structure and/or site to reduce the potential failure
- (2) Abandoning the structure if the retrofit costs exceed the potential benefits derived from maintaining the structure
- (3) Accepting the risk and maintaining the existing use

Additional options would be to continue the use of the structure but to change the operation or to alter the use of the structure such that the hazard becomes tolerable even if failure occurs.

For new construction, moving the project assumes that there are alternative sites, where liquefaction hazard is not a concern, but is equally appropriate for the proposed project. The costs of necessary mitigation actions may, in some cases, make selection of an alternative site a more cost-effective alternative than the use of the primary site. The choice of accepting the risk associated with the hazard, and the potential loss of life, social disruption, economic loss, and political ramifications that might result from structural failure, must be based on engineering evaluation of the site.

Thus, the overall goal of any remediation work is to investigate alternatives to mitigate the liquefaction hazard so that relative benefits versus costs for different levels of mitigation efforts can be assessed. In investigating potential remedial measures, the following factors should be considered:

- Technical adequacy
- Field verifiability
- Costs

Liquefaction: Countermeasures to Mitigate Risk

Introduction

Past several earthquakes have vividly demonstrated the impact of soil liquefaction and the associated ground deformations to buildings, bridges, buried lifelines, and other civil infrastructure. To reduce the risk of damage to the structures, remediation measures are usually

- Maintenance
- Long-term performance
- Environmental impact

In this section, general descriptions of the principles involved in ground improvement methods, i.e., densification, solidification, drainage, reinforcement, containment, and soil replacement, as well as some representative methods, are presented. Verification techniques and design issues associated with general ground improvement methods are also explained.

General Description of Countermeasures

Countermeasures to mitigate the damaging effects of liquefaction can be classified into two categories: (1) ground improvement (to remediate liquefiable soils) and (2) structural enhancement (to relieve the effects of liquefaction). Some projects may require the combination of the two methods.

Ground improvement, whose goal is to limit soil displacements and settlements to acceptable levels, is being used increasingly for remediating liquefiable soils due to the wide variety of methods that are available. These methods can be modified and customized to specific site settings, including space/operation restrictions and the presence of existing structures. In addition, one or more methods can often provide economical solutions for liquefaction remediation problems.

Ground improvement methods are generally based on one or more of the following principles:

- Densification
- Solidification
- Drainage
- Reinforcement and containment
- Soil replacement

Descriptions of the principles behind the improvement mechanism associated with each category are provided below, along with some particular treatment techniques in the category

that can potentially be used at existing structures and for future sites. In addition, some design considerations are also briefly described. Details concerning the specific treatment methods can be found in references on ground improvement (e.g., Cooke and Mitchell 1999; Andrus and Chung 1995; Xanthakos et al. 1994; Hausmann 1990; JGS 1998; PHRI 1997). Note that there is no attempt herein to provide a comprehensive discussion of all available liquefaction countermeasures; rather, only representative methods are discussed for each improvement mechanism. Moreover, new techniques are being developed when difficult circumstances are encountered in the field, while available techniques are being refined to suit the requirement of the problem. Thus, more and more ground improvement techniques are becoming part of the expanding set of available mitigation measures.

Structural enhancement can reduce the damage to the structure while allowing liquefaction to occur. Examples include strengthening the foundations of the structures and the ground supporting the structures to avoid reduction of bearing capacity or possible uplift due to soil liquefaction. The use of flexible structures, which can deform together with the ground deformation, is a viable option for underground structures.

It should be mentioned that mitigation of liquefaction risk is an area subject to considerable controversy and that the current understanding of the efficacy of some of these methods is still evolving (Seed et al. 2003). Moreover, while the case histories clearly indicate that ground improvement leads to a significant decrease and/or elimination of large liquefaction-induced ground deformations, the data is not yet sufficient to be able to predict the ground deformations for a given set of site conditions and earthquake motion (Hausler and Sitar 2001). Furthermore, large earthquakes which can verify the effectiveness of these techniques are infrequent and current database of observed field performance has marginal quality. Fortunately, this is being addressed by more detailed studies of the field case histories (e.g., Yasuda et al. 1996; Ishii et al. 2013) coupled with carefully designed experimental testing and numerical analyses.

Densification Methods

Densification or compaction methods involve rearranging the soil particles into tighter configuration, resulting in increased density. This increases the shear strength and liquefaction resistance of the soil and encourages a dilative instead of a contractive dynamic soil response. Densifying loose sandy deposit with vibration and/or impact has been used extensively, making it the most popular liquefaction countermeasure.

An increase in soil density can be achieved through a variety of means (JGS 1998). These include (1) compaction by penetration (penetration of sandy material into the liquefiable deposit will push the surrounding soil and result in reduced void ratio and therefore increase in soil strength), (2) compaction by vibration (subjecting the loose sandy deposit to vibration energy will compact the soil and increase its strength), and (3) compaction by impact energy (impact energy can densify loose granular deposit).

The suite of methods which involve compaction by displacement and/or vibration involves a vibrating probe repetitively penetrating the ground to densify the liquefiable soils and is generally referred to as *vibromethod*. These methods involve various kinds of equipment and procedures and are known by some generic or proprietary names. The simplest categorization of vibromethods is as follows:

- Vibro-replacement: the cavity formed by probe penetration is filled with imported materials, such as crushed stone gravel and sand.
- Vibro-flotation: the surrounding soil is compacted with a horizontally vibrating motor attached to the end of the probe, sometimes aided by water sprayed from the nozzle tip end.
- Vibro-rod: compaction is achieved using vertical vibratory penetration to the top of the probe or rod.
- Vibratory tamper method: a rigid steel plate (tamper) attached to a vibrator at the surface of the ground to compact the surface soil.

Vibro-replacement methods can improve liquefiable soil deposits not only by densification

but also by increasing the in situ lateral stress, replacing the liquefiable in situ soil with non-liquefiable material, reinforcing the original ground with stiffer columns of fill materials, and providing drainage paths for excess pore water pressure. Two of the most widely implemented methods are the sand compaction pile (SCP) method (popular in Japan) and stone column (SC) method (common in the United States). Sand compaction piles are constructed by driving a sand-filled steel casing into the ground after which the casing is then slowly withdrawn and the deposited sand is compacted to form a high density sand column (Schaefer 1997; JGS 1998). The sand backfill must have specific properties and sometimes may be difficult to source. Recent case histories indicate that metal slag, crushed oyster shell, granulated fly ash, or recycled crushed concrete and asphalt are feasible alternatives to sand (Kitazume 2005). A variation on the sand compaction pile technique is the use of gravel backfill, to create stone columns (Munfakh et al. 1987; Sondermann and Wehr 2004). Generally the fill material consists of crushed coarse aggregates of various sizes, with the ratio in which the stones of different sizes will be mixed decided by design criteria.

Vibro-flotation method compacts loose soil by inserting a horizontally vibrating vibroflot into the ground while jetting water from the bottom end of the vibroflot, followed by gradually extracting it while forcing sand or gravel from the ground surface into the voids created adjacent to the vibroflot. On the other hand, vibro-rod method involves driving a vibrating rod or pile into the liquefiable soil, thereby causing it to locally and temporarily liquefy, after which new sand is placed along the rod or pile to densify the in situ soil. In vibro-flotation and vibro-probe methods, sand or gravel fill is injected from the ground surface into the voids created in the original ground during vibration.

Dynamic compaction involves repetitively dropping a large weight from a significant height onto the ground causing the soil grains to rearrange and form a denser arrangement. Additionally, the impact of the dropped weight on the ground surface produces dynamic stress waves,

which can be large enough to generate significant excess pore water pressure in the soils beneath the point of impact (Idriss and Boulanger 2008). The dissipation of these excess pore water pressures results in densification, accompanied by surface settlement. The drop height, weight, and spacing vary, depending on ground and groundwater conditions. Dynamic compaction is known to be fast and economic, especially in treating large areas. However, it has obvious disadvantages due to the noise and vibration that are produced. Moreover, it is often effective only in the upper 10 m of the deposit and it is less effective for soils with high fines content.

In compaction grouting, a very stiff grout is injected into the soil such that it does not permeate the native soil, but results in coordinated growth of the bulb-shaped grout that pushes and displaces the surrounding soil. Typically the grout consists of soil–cement–water mixture with sufficient silt sizes to provide plasticity, together with sand and gravel sizes to develop internal friction (Welsh 1992). Note that the strength of the grout is unimportant because the purpose of the technique is to densify the surrounding soil by displacement. Since the technique involves the pressurized injection of grout into the soil deposit using small-scale, maneuverable, and vibration-free equipment, there is minimum disturbance to the structure and surrounding ground during implementation. Additional advantages include relatively little site disruption and the ability to work in constricted space, resulting in greater economy. However, it has some disadvantages; for example, stabilization of near-surface soils is generally ineffective due to the fact that the overlying restraint is small and the grouting pressures can heave the ground surface rather than densify the soil.

Compaction by man-made explosions can also be employed to densify loose liquefiable deposits. By detonating explosive charges placed at various depths in boreholes across the site in a controlled manner, the explosions propagate dynamic shear stresses through the ground which can induce liquefaction. The post-liquefaction consolidation following the

dissipation of excess pore water pressure results in densification of the soil, together with ground settlement (Narin van Court and Mitchell 1994; Maeda et al. 2006). This method is effective in sites where cleaner loose sands, which will undergo relatively large and rapid reconsolidation, are present at greater depths. Conversely, it may be less effective in densifying shallow deposits.

In general, densification or compaction methods are more suitable for use in saturated, cohesionless soils with a limited percentage of fines. They cause noise and vibration during installation and also increase horizontal earth pressures against adjacent structures. This increase in pressure is the major disadvantage of using compaction methods in close proximity to retaining walls and pile foundations. The major advantage of compaction methods is the relatively low cost/benefit ratio. The necessary degree of compaction can be evaluated using penetration resistances that have been back-calculated from an acceptable factor of safety against liquefaction.

Solidification Methods

Increase in liquefaction resistance can also be obtained through a more stable skeleton of soil particles. This can be achieved by solidification methods, which involve filling the voids with cementitious materials resulting in the soil particles being bound together. This will prevent the development of excess pore water pressure, preventing the occurrence of liquefaction. Typical methods include deep mixing method, premixing method, and grouting techniques.

The deep mixing method achieves liquefaction remediation by agitating and mixing stabilizing material such as cement in sandy soil and solidifying the soil. The soil–cement materials in the mixed columns can have a wide range of unconfined compressive strengths, depending on the amount of cementitious material used and the in situ soil characteristics (Kitazume and Terashi 2013). This technique can be applied over a whole area of liquefiable soil (block type) or over partial sections (wall type, pile type, or lattice type). In block type, the mix columns

overlap each other, and the whole layer is improved due to the increased stiffness. In partial improvement, unimproved sections remain and may liquefy; however, depending on the shape of installation, the mix columns are effective in preventing liquefaction by restraining the shear deformation of the ground through reinforcement and confinement, as described below.

The premixing method, on the other hand, is done by adding stabilizing material to the soil in advance and placing the treated soil at the site (JGS 1998). This is recommended for constructing new reclaimed land or in filling behind caissons, allowing both reclamation work and anti-liquefaction measures to be implemented at the same time to develop stable ground.

Chemical grouting, sometimes called permeation grouting, is a technique that transforms granular soils into hardened soil mass by injecting cement or other grouting materials that permeate and fill the pore space. The hardened grout improves the native soil by cementing the soil particles together and filling the voids in between (minimizing the tendency of the soil to contract during shearing). The treated soil would have increased stiffness and strength and decreased permeability. Because of its minimal disturbance to the in situ soil, it is an effective method in treating liquefiable deposits adjacent to existing foundations or buried structures.

In jet grouting, high-pressure jets of air, water, and/or grout are injected into the native soil in order to break up and loosen the ground and mix it with thin slurry of cementitious materials. In essence, it is not truly grouting but rather a mix-in-place technique to produce a soil-cement material. Depending on the application and soils to be improved, different kinds of jet are combined by using single fluid system (slurry grout jet), double fluid system (slurry grout jet surrounded by an air jet), and triple fluid system (water jet surrounded by an air jet, with a lower grout jet). The process can construct grout panels, full columns, or anything in between (partial columns) with a specified strength and permeability.

Solidification techniques can generally be used in a wide range of soil types, including those with high fines content. They are

advantageous because the installation methods are relatively quiet and induce relatively small vibrations as compared to compaction methods. The induced horizontal earth pressures are smaller than with compaction methods and are larger than with drainage methods. Their disadvantage is the relatively high cost/benefit ratio as compared to compaction and drainage methods.

Drainage Methods

Excess pore water pressure generated by cyclic loading can be reduced and/or dissipated by installing permeable drain within the deposit. The methods employed can be divided into two categories depending on the material used as drain: grave drain and artificial drain methods. These methods rely on two mechanisms to reduce damage due to liquefaction: (1) delaying the development of excess pore water pressure due to earthquake shaking and (2) preventing the migration of high excess pore water pressure from untreated liquefied zones into non-liquefied areas (say underneath the structure) to prevent secondary liquefaction caused by pore water pressure redistribution.

Gravel drains are typically installed either as column-like drains in a closely spaced grid pattern or as backfill around underground structures to control the levels of maximum excess pore water pressure ratio during earthquake shaking. They can also be installed as wall-like or column-like perimeter drains at both sides of densified (treated) zones or to isolate the high excess pore water pressure from liquefied areas. In the installation of gravel drains, casing with an auger inside is drilled into the ground down to the specified depth. Crushed stone is then discharged into the casing and the gravel drain is formed by lifting the casing pipe.

Artificial drains can be made of geosynthetic composites or piles with drainage functions. They have not only drainage effect but also reinforcing effect. For example, plastic drain consists of a plastic perforated pipe drainage skeleton wrapped in geofabric to prevent clogging from soil particles. These can be easily installed; however, close spacing is usually required due to the limited capacity of each drain.

Design charts for drains were initially developed by Seed and Booker (1977) to control the maximum excess pore water pressure levels, but more recent design charts and analytical methods (e.g., Iai and Koizumi 1986; Pestana et al. 1997) provide better methods of taking into account various factors affecting the drain performance, such as the hydraulic properties of the drain and permeability and volumetric compressibility of the native soil.

Drainage remediation methods are suitable for use in sands, silts, or clays. One of the greatest advantages of drains is that they induce relatively small horizontal earth pressures during installation. Therefore, they are suitable for use adjacent to sensitive structures. In the design of drains, it is necessary to select a suitable drain material that has a coefficient of permeability substantially larger than the in situ soils. Installation can be carried out with low noise and vibration. However, since the in situ soils improved by this method remain in a loose condition, the method has obvious disadvantages when compared to compacted deposits, such as negligible ductility and significant residual settlement of the treated soils. It is effective only if it successfully promotes sufficiently rapid dissipation of pore pressures as to prevent the occurrence of liquefaction; if pore pressure dissipation is not sufficiently rapid during the relatively few critical seconds of the earthquake, this method does relatively little to improve post-liquefaction performance (Seed et al. 2003). Thus, the method is usually combined with densification method, i.e., the surrounding ground is compacted to some extent during the drain installation.

Replacement Methods

The remove and replace method is another liquefaction mitigation technique. This involves the removal of the in situ liquefiable material and replacement with a non-liquefiable material such as clay, gravel, or dense sand. Its advantage is that it provides high degree of confidence in the final product and uses construction equipment and practices that are widely available and easily tested (Idriss and Boulanger 2008). However, this method is only feasible when relatively small

volumes of liquefiable material are involved at shallow depths.

Reinforcement and Containment Methods

When saturated sand deposits are sheared during seismic loading, excess pore water pressure is generated. To prevent the occurrence of liquefaction, the soil should undergo smaller shear deformation during earthquake. This can be achieved by underground diaphragm walls, sheet piles, or lattice-shaped walls using deep mixing techniques. This method simply surrounds the liquefiable soil with continuous underground wall, and thus, it can be used for the soil at the bottom of existing structures where liquefaction remediation is difficult with other methods. The shear deformation in the ground is reduced during an earthquake to mitigate liquefaction and at the same time provide support to the overlying structure. It can also be used to prevent excessive deformation of structures by restraining the lateral flow of ground after liquefaction.

The presence of stone columns, timber piles, and other stiff elements provide additional shear resistance against earthquake shaking. These reinforcements would take much of the earthquake load, thereby minimizing the shear deformation of the soil.

The key advantages of the method include (1) less vibration and noise, (2) applicable to existing structures, (3) no restriction to soil type and depth, and (4) effective use of land due to smaller treatment area. On the other hand, disadvantages of the method are the (1) lack of simplified methods to evaluate effectiveness and (2) generally higher construction costs.

Increasing In Situ Stress

In situ effective stresses within the soil mass can be increased, resulting in an increase in shear resistance. Pre-loading involves overconsolidating the soil with surcharge embankment by initially inducing increased vertical and horizontal effective stresses, and when the surcharge is removed, the resulting overconsolidation leaves the in situ soil somewhat more resistant against liquefaction. This method is applicable to soils with large fines content and can also be applied

even below existing structures since the soil can be overconsolidated.

Lowering the groundwater table makes the soil above the water table unsaturated, resulting in increased effective stress for soils below the water table. In addition, if the water table is reduced to a level below the liquefiable soil layer, liquefaction is prevented because the absence of water makes the buildup of excess pore water pressure impossible (Cox and Griffiths 2010). For this method, it is always necessary to maintain the lower groundwater level, and this may result in higher operating cost and maintenance cost associated with continuous pumping. Thus, this technique is typically limited to short-term applications.

Structural Strengthening Techniques

There are many types of measures which can be adopted to minimize damage to structures while allowing the occurrence of liquefaction itself. The selection of the appropriate remedial measure depends on the type of structure and the results of assessment of the required stability of the structure considering the effect of liquefaction, e.g., loss of bearing capacity, increase in earth pressure, etc. Several structural strengthening techniques implemented to various structures are described below.

Deep foundations, such as piles or piers whose lengths extend below the occurrence of liquefaction (or significant cyclic softening due to partial liquefaction), can provide reliable vertical support and so can reduce or eliminate the risk of unacceptable liquefaction-induced settlements. However, pile or pier foundations do not necessarily prevent damages that may occur as a result of differential lateral structural displacements, so piles and/or piers must be coupled with sufficient lateral structural connectivity at the foundation as to safely resist unacceptable differential lateral displacements. Moreover, pile foundations are likely to be damaged by lateral forces caused by a decrease in subgrade reaction accompanying liquefaction and associated lateral spreading of liquefied soil. To reduce the damage from such ground deformations, inclined piles or large-diameter vertical piles have frequently been

used, or the number of piles has been increased. Moreover, significant research efforts over the past 20 years have led to the development of a range of methods to address the effect of laterally spreading ground on pile foundations, ranging from simplified pseudo-dynamic approach (e.g., Hamada et al. 1986; Cubrinovski et al. 2012) to fully nonlinear, time-domain, fully coupled effective stress analysis of soil/pile/superstructure interaction analyses (e.g., Iai et al. 1998; Bowen and Cubrinovski 2008). These types of methods, complemented with appropriate conservatism, can provide a suitable basis for analysis of this issue and for the design and detailing of piles (or piers) and pile/cap connections.

In structures with spread foundations, differential settlement and cracks in foundation can occur as a result of loss in bearing capacity of foundation ground following liquefaction. To address this, spread foundations can be supported by piles. In addition, stiff, reinforced shallow foundations are used to resist both differential lateral and vertical displacements. Japanese practice has increasingly employed both grade beams and continuous reinforced foundations for low to moderate height structures, and performance of these types of systems in earthquakes has been good. Note that although stiff, shallow foundations can undergo differential settlements resulting in rotational tilting of the structure; these can be easily re-leveled after earthquake-induced settlements through several techniques, including jacking, under-excavation, or compaction grouting.

Quay walls can become unstable because of increase in active earth pressure and reduction in passive earth pressure. To prevent damage to such waterfront structures, strong quay walls such as pile-supported quay walls have been employed.

Buried pipelines may be bent, compressed, or extended as a result of large-ground displacement induced by liquefaction. Underground tanks are likely to be uplifted as a result of high excess pore water pressure developing underneath. For buried pipes, flexible joints have been used to absorb the large-ground deformation while some pipes have been supported by pile foundations. To prevent floating of underground structures,

counterweights are usually placed on top of the structure or the structure is supported by piles.

When the foundation ground liquefies or softens, embankments built on top may slide or settle due to the decrease in bearing capacity. Possible countermeasures that can be used include installation of sheet piles on both edges of the embankment connected by tie rod or placement of berms and counterweight fills to minimize damage to the embankments.

Verification of Effectiveness

After the appropriate remediation technique has been selected and applied to the target site, attempts should be made to verify that the desired level of improvement has been achieved. It is no longer an acceptable practice to simply implement mitigation; the adequacy of the mitigation must also be evaluated.

The most direct way of effectiveness verification is to compare the soil characteristic which was deemed deficient before and after the improvement. For example, if the remediation was performed to increase the strength of the soil, then strength measurements before and after the improvement would be necessary to confirm the effectiveness of the chosen technique. In some cases, direct verification of the target characteristic may not be feasible and checking of related characteristics can be done more easily.

Laboratory Testing Techniques

Verification of the effectiveness of improvement technique through laboratory tests, such as triaxial tests, simple shear tests, and torsional shear tests, offers several advantages and disadvantages. One of the merits of these element tests is that by obtaining soil samples before and after improvement, a more direct inspection can be made. In addition, more accurate measurement of stress, strain, and other parameters can be performed, and therefore, a more accurate characterization of the improved soil is possible.

On the other hand, since soil sampling has to be done only at several representative locations, verification of effectiveness only at these discrete

points can be made and not throughout the whole target area. Moreover, the effect of sample disturbance during sampling, handling, and transportation can have adverse effects on the characteristics of the sample which could affect the verification process.

In Situ Testing Techniques

By far, the most popular approach of checking the level of improvement is by performing in situ tests before and after the treatment process. Procedures like the standard penetration tests (SPT), cone penetration tests (CPT), flat plate dilatometer tests, and pressure meter tests are quite common. This approach has the advantage that the in situ tests can be done quickly, especially the SPT and CPT, and therefore, the level of improvement can be immediately assessed.

However, the results of these in situ tests should be interpreted carefully. For example, the SPT N-value is affected not only by density and confining pressure but also by lateral stress. Therefore, evaluating liquefaction potential using simplified approaches based on SPT N-values alone should be done with caution. These semiempirical methodologies are typically defined for normally consolidated soils, while ground improvement techniques can undoubtedly alter the soil's density, lateral stress, stress and strain history, fabric, and prior effect of ageing. Moreover, the time-dependent nature of the improvement should be considered. Results obtained immediately after the implementation of ground improvement technique may not represent the long-term effect of the technique due to factors like stress redistribution, creep-induced relaxation in lateral stress, etc. In addition, the location of in situ tests and location of treatment points should be considered. For example, to evaluate the effectiveness of sand compaction pile method, it has been customary to perform the penetration test at the center of the grid of sand piles, deemed as the point where the effectiveness of sand compaction is weakest.

Geophysical Testing Techniques

Another approach to verification is through direct transmission seismic testing, such as downhole

and cross-hole seismic testing as well as spectral analysis of surface waves (SASW), which provides calculation of improvement values with some accuracy. In this procedure, the velocity of seismic waves, which is a function of basic soil properties such as modulus of elasticity, density, and Poisson's ratio, is measured between two points and this can give a more accurate picture of the level of improvement as compared to traditional penetration tests. Seismic reflection and refraction tests can be performed to verify the effectiveness of the technique for a wide area.

Design Issues in Ground Improvement

Several factors influence the stability and deformation of improved ground zones and supported structures during and after an earthquake (PHRI 1997; JGS 1998; Mitchell et al. 1998). Some of the more important factors are discussed below.

Size, Location, and Type of Treated Zone

Even when a wide area of soil undergoes liquefaction, the zone requiring soil improvement is generally limited to the area which directly affects the stability of the structure. For example, the portion of the subsoil which provides stability to structures on spread foundation is that directly underneath and on the perimeter of the structure; the portion of the subsoil at considerable distance from the structure has negligible effect on the stability of the said structure. The question then boils down to how wide the soil improvement should be.

In practice, the region to be remediated should be determined in both horizontal and vertical directions. For the vertical direction, it is usual practice to improve the ground to the deepest part of the liquefiable layer. If only the shallow portion of the liquefiable layer is improved, the excess pore water pressure generated at the bottom of the unimproved soil, if it liquefies, may induce upward seepage towards the surface and may result in potential instability at the upper improved zone. As for the lateral extent of treatment necessary, this is dependent on the type of remediation measure employed and the allowable

deformation the structure can undergo. This can be investigated by performing detailed analysis and, if possible, supplemented by model tests. In many cases, the lateral extent of treatment beyond the edge of the structure is a distance equal to the depth of treatment beneath the structure.

Pore Pressure Migration

The difference in stiffness between a compacted zone of material and the surrounding loose liquefiable material could result in seepage between these two materials during and after earthquakes. Higher excess pore water pressure is developed in the untreated material, resulting in propagation into the adjacent improved soil. Although the effect of pore pressure migration into a dense material is very complex, it may nevertheless lead to strength loss of the densified soil.

Ground Motion Amplification

Due to the increase in its stiffness, remediated ground may induce an increase in ground motion, and this may be disadvantageous to the structure on top of it. Although little information is available regarding the influence of size of improved ground and its stiffness on ground motions, engineers should consider a balance in design such that the size and stiffness of the remediated ground would result in acceptable deformations and ground accelerations of the structure during an earthquake.

Dynamic Fluid Pressure

At the boundary between the improved and unimproved ground, both dynamic fluid pressure and static pressure corresponding to earth pressure coefficient equal to 1.0 are applied due to the liquefaction of the untreated ground. These forces must be taken into account when investigating the stability and deformation of structure supported in the improved zone.

Inertia Force

The dynamic response of the improved ground may change as a result of the liquefaction of the unimproved soil and the migration of excess pore

water pressure, leading to a change in the inertia force on the improved ground. This inertia force should be included when evaluating the stability of an improved ground zone supporting a structure. Note however, that the phasing between inertia forces acting on the improved ground and supported structure may be different and this can have significant impact on the results of simplified stability and deformation analyses.

Influence of Structure

The existence of a structure either on top of or adjacent to an improved ground will change the stress state within the said zone and can affect the dynamic response and stress–strain behavior of the improved soil. The effects would depend on the soil and structure conditions, as well as on the installation process.

Forces Exerted by Laterally Spreading Soil

Liquefaction-induced lateral ground movements have been observed to occur at gently sloping sites, with gradients less than 1 %. Therefore, the improved ground should be sufficiently designed to resist the forces induced by the laterally moving ground. There are two force components that should be considered: first, the load exerted by the moving liquefied ground itself, and second, the force exerted by the unliquefied surficial crust riding on top of the liquefied ground.

Summary

Various remediation techniques are available to mitigate the liquefaction risk to structures constructed on loose saturated sandy deposits. These techniques can be roughly classified into two groups: the first is to improve the soil so that liquefaction may not occur, while the second is to provide measures for structures to prevent or minimize damage even if liquefaction occurs. Remedial treatment of soils to prevent liquefaction is based either on the principle of improving the properties of soils or the principle of changing stress or deformation conditions. In some cases, liquefaction is allowed to occur, but the damage

is prevented or minimized by strengthening the structure or foundations.

Ground improvement is being used increasingly for remediating liquefiable soils due to the wide variety of methods that are available. Backed by several decades of research and experience, these methods have been utilized in many soil conditions and have been developed by both the construction industry and research institutions. These techniques can be adapted to site-specific conditions and, in some cases, one or more methods being combined to provide economical solutions for liquefaction remediation problems. Often, new ground improvement techniques are developed when difficult circumstances are encountered and these new techniques are then refined and become part of the expanding set of available mitigation measures.

A few of the remediation methods which have been implemented at many sites all over the world have been tested by few large-scale earthquakes, and most of them performed well, with negligible or minor ground damage. Thus, these remediation techniques will continue to play an important role in the mitigation of seismic risk to existing and future structures.

Synonyms

Building settlement on softened ground; Shallow-founded structures on liquefiable soils; Soil-structure-interaction on softened ground

Definition

When founded on liquefiable ground, building response is commonly evaluated by the geotechnical engineer and structural engineer in a decoupled manner. The geotechnical engineer evaluates the potential for liquefaction triggering under a likely earthquake scenario (in most cases ignoring the presence of the structure), assesses the resulting building settlements, and typically designs a mitigation strategy to prevent liquefaction from occurring or to reduce settlements. On the other side, the structural engineer typically evaluates the seismic performance of the structure under fixed-base conditions (no soil-structure interaction considered), assuming that the liquefaction hazard is mitigated or bypassed. In performance-based structural design, the building *performance* is evaluated in terms of critical engineering demand parameters that correlate well with its damage potential (e.g., inter-story drift). In this article, the *performance* of a building on liquefiable ground is mainly discussed from the geotechnical engineer's viewpoint: the settlement potential.

Introduction

Liquefaction continues to pose a significant risk of damage to the built environment, as observed in both New Zealand and Japan in 2011 (e.g., Fig. 1). More than 50 % of the Christchurch area in New Zealand was affected by soil liquefaction during the 2011 Christchurch earthquake (Fig. 2). Damage caused by settlement, tilt, and lateral sliding, which mostly affected buildings on shallow foundations and their surrounding lifelines, caused severe economic losses (Green et al. 2011; Cubrinovski and McCahon 2012). In many cases, the structures were uneconomical to repair and were demolished. Future earthquakes in major cities around the world are expected to continue causing liquefaction-related damage.

Effective mitigation of the soil liquefaction hazard requires a thorough understanding of the potential consequences of liquefaction and the building performance objectives. The consequences of liquefaction in terms of ground displacement, in turn, depend on site conditions, earthquake loading characteristics, and building properties. This article provides an overview of

the state of practice in evaluating liquefaction-induced building settlements in geotechnical engineering. A summary of observations from recent case histories, physical model studies, and numerical analyses is presented to provide recommendations for practice and future research.

**Background and Developments in
Liquefaction Engineering**

State of Practice in Evaluating Liquefaction-Induced Building Displacements
Figure 3 provides an overview of the various steps used to analyze the likelihood and impact of liquefaction in design and building assessment (Seed et al. 2003). The process starts by assessing the likelihood of liquefaction triggering (e.g., Youd et al. 2001; Seed et al. 2003). If the soil is

**Liquefaction:
Performance of Building
Foundation Systems,
Fig. 3** Steps in
liquefaction engineering
(Adapted from Seed
et al. 2003)

judged to liquefy during the expected earthquake scenario, the overall stability of the foundation is evaluated using the available post-liquefaction,

residual soil strength to avoid failure and large deformations. If overall stability is not a concern, the consequences of liquefaction need to be evaluated in terms of building displacement. The evaluation of liquefaction-induced building settlements and the impact of those settlements on building performance (highlighted boxes in Fig. 3, which are discussed in this article) are currently steeped in empiricism with significant uncertainties (Seed et al. 2003).

Liquefaction-induced settlements are commonly estimated using simplified empirical procedures (e.g., Tokimatsu and Seed 1987; Ishihara and Yoshimine 1992), which were based on undrained cyclic laboratory tests on samples of saturated, clean sand. These empirical procedures evaluate post-liquefaction, volumetric reconsolidation settlements due to the dissipation of excess pore water pressures after cyclic loading. These methods have generally compared well with previous case histories and physical model studies in the free field or away from buildings. They, however, ignore the presence of the structure and the displacement mechanisms that are active under its foundation. Therefore, these procedures may be misleading in assessing the extent of building settlement and subsequent damage.

To bring in the influence of a structure, practicing engineers often use a combination of (1) empirical methods (e.g., Tokimatsu and Seed 1987; Ishihara and Yoshimine 1992) with the added confining pressure of the structure and (2) case history observations of the effect of foundation width on foundation settlement both normalized by liquefiable layer thickness (Liu and Dobry 1997). In current practice, if the estimated settlements obtained in this manner are judged to be excessive, mitigation techniques are considered to reduce the settlements to an acceptable level or to avoid soil liquefaction altogether. The same empirical procedures as above are then used to evaluate the effectiveness of the proposed mitigation techniques (e.g., ground improvement) in terms of reduction in settlement.

There are presently no well-calibrated, simplified design procedures for estimating the combined and complex effects of deviatoric and

volumetric settlements due to cyclic softening under the static and dynamic loads of structures. This is in contrast with those procedures available for evaluating liquefaction triggering and post-liquefaction reconsolidation settlements in the free field. The lack of a proper understanding of the dominant displacement mechanisms near a building and a reliable analytical tool for estimating liquefaction-induced building settlements has sometimes resulted in the implementation of inadequate hazard mitigation measures (as observed during the 1999 Kocaeli earthquake in Turkey).

Case Histories of Liquefaction-Induced Building Damage

Observations of building performance on liquefied sites during previous earthquakes showed punching settlement, bearing failure, tilt, and lateral shifting of buildings. In the 1964 Niigata (Japan) and the 1990 Luzon (Philippines) earthquakes, most of the damaged buildings were two to four stories, founded on shallow foundations and relatively thick and uniform deposits of clean sand. The confining pressure and shear stress imposed by the buildings and their adjacent structures on the soil affected building movements (e.g., Tokimatsu et al. 1994). Contrary to previous case histories, in the 1999 Kocaeli (Turkey) earthquake, many of the damaged structures were influenced by the liquefaction of thin deposits of silt and silty sand (Sancio et al. 2004; Bray et al. 2000; Bird and Bommer 2004). The building settlement was directly proportional to its contact pressure, and the building's height/width (H/B) aspect ratio greatly affected the degree of tilt (Sancio et al. 2004), showing the importance of the building's dynamic properties. Some buildings translated laterally up to 1 m.

More recently, liquefaction-induced settlements of 1–2 m and tilts exceeding 2° were observed in low- to mid-rise structures in the M_w 6.1, 2011 Christchurch, New Zealand, earthquake. Ground motions recorded on liquefiable sites showed amplified spectral content for periods greater than 2 s. The uplift forces from groundwater pressures caused floors to bulge upward and the foundations to damage and tilt

due to lateral spreading (Cubrinovski and McCahon 2012). Similarly, during the M_w 9, 2011 Tohoku-Kanto earthquake in Japan, the building damage in the Kanto region was dominated by liquefaction, not ground shaking alone (Ashford et al. 2011).

Despite these well-documented case histories, the relation between key ground motion characteristics, soil properties, and the response of building (in terms of settlement, tilt, lateral displacement, and subsequently building performance and damage potential) associated with soil liquefaction, with or without remediation, is not well understood. Buildings that are significantly tilted may need to be demolished and rebuilt, representing a complete loss, despite having a rigid body rotation and intact structural components. On the other hand, there may also be cases in which the liquefied soil, serving as a base isolator, reduces shaking-induced damage to structures by dissipating energy and altering motion frequency content.

Physical Model Studies of Shallow-Founded Structures on Liquefiable Sand

Because of the uncertainties involved in interpreting case histories and limited instrumental recordings at key locations, physical modeling under controlled and simplified conditions provides valuable insights to improve the understanding of liquefaction and its effects. Several researchers have used reduced-scale shaking table and centrifuge tests in the past to study the response of rigid, shallow model foundations situated atop deposits of saturated, loose to medium dense, clean sand (e.g., Yoshimi and Tokimatsu 1977; Liu and Dobry 1997; Hausler 2002; Madabhushi and Haigh 2010).

In a recent study, centrifuge experiments were performed to identify the dominant mechanisms of building settlement on relatively thin and shallow deposits of liquefiable, clean sand (Dashti 2009; Dashti et al. 2010a). These tests employed elastic, single-degree-of-freedom (SDOF) structural models with realistic fundamental frequencies (as opposed to a rigid foundation) on liquefiable ground (as shown in Fig. 4). Structures and the soil adjacent to the structures settled

significantly more than the soil in the free field (soil away from the structures) in most cases, as shown in Fig. 5 for a representative test. These comparisons demonstrate the inadequacy of using empirical, free-field procedures to evaluate building settlements.

A strong tendency for flow away from the structures toward the free field was observed during stronger shaking events, which likely led to localized volumetric strains due to partially drained cyclic loading (Dashti et al. 2010a). The relative influence of various testing parameters and structural properties was investigated. Conceptually, the study classified the primary settlement mechanisms as (a) volumetric types, rapid drainage during cyclic loading (ϵ_{p-DR}), sedimentation (ϵ_{p-SED}), and consolidation due to excess pore pressure dissipation (ϵ_{p-CON}) and (b) deviatoric types, partial bearing capacity loss under the static load of the structure (ϵ_{q-BC}) and soil-structure interaction (SSI)-induced building ratcheting under the dynamic load of the building (ϵ_{q-SSI}).

Dashti et al. (2010a) showed that building settlement is not proportional to the thickness of the liquefiable material, as volumetric settlements may not be dominant underneath a structure. As long as there is sufficient thickness of liquefiable soils present under the building, significant settlements may be observed due to deviatoric or shear-induced strains. Hence, the available empirical charts of building settlement that are normalized by the thickness of liquefiable layer may be misleading and should not be used in the engineering practice.

The relative importance of the identified displacement mechanisms, which affects the choice of an effective remediation strategy, depended strongly on several parameters: the liquefiable soil's initial relative density (D_r) and thickness, flow boundary conditions, and ground shaking intensity and the building's fundamental frequency, foundation geometry, and contact pressure. Further, centrifuge experiments revealed that the settlement time history of buildings during each earthquake followed the shape of the Arias Intensity time history of the motion, as shown by the representative results in Fig. 6.

Liquefaction: Performance of Building Foundation Systems, Fig. 4 Centrifuge experiment by Dashti (2009): (a) schematic drawings (plan and elevation views) of a representative test with three SDOF structures

with different properties and (b) picture of model building C used in centrifuge testing. Dimensions shown in prototype scale meters (when the model was spun to 55 g of centrifugal acceleration)

Liquefaction: Performance of Building Foundation Systems, Fig. 5 Settlement of different structures compared to the free field and the adjacent soil during a

representative centrifuge experiment T3-30, with liquefiable layer thickness of 3 m and relative density of 30 % (Adapted from Dashti 2009)

Liquefaction: Performance of Building Foundation Systems, Fig. 6 Settlement time history of the baseline structure (BL) and free field soil surface compared to the corresponding Arias Intensity time history of the base motion during a representative centrifuge experiment T3-50, with liquefiable layer thickness of 3 m and relative density of 50 % (Adapted from Dashti et al. 2010b)

Arias Intensity (I_a) is an index representing the energy of the ground motion in units of L/T (Arias 1970) and defined as

$$I_a(T) = \frac{\pi}{2 \cdot g} \int_0^T a^2(t) \cdot dt \quad (1)$$

over the time period from 0 to T , where a = the measured acceleration value. The Arias Intensity of an earthquake motion depends on the intensity, frequency content, and duration of the ground motion. Its rate represents roughly the rate of earthquake energy buildup. These preliminary experimental results show the importance of taking into account holistic ground motion intensity parameters (e.g., I_a or its slope) in the selection of ground motions for design.

Numerical Studies of Liquefaction Effects

In analytical studies, Soil-Foundation-Structure Interaction (SFSI) effects are commonly evaluated employing equivalent linear, visco-elastic soil models. In reality, the soil response is nonlinear, particularly when it undergoes a significant strength loss and softening as in liquefaction. The insight gained from the previous case histories and physical model studies (summarized in the previous sections) points to the need for performing fully coupled, effective stress, nonlinear dynamic analysis of the soil-structure system, to capture the interacting influences of the key factors on soil and structural response. Popescu and Prevost (1993), Elgamal et al. (2005), Popescu et al. (2006), Andrianopoulos et al. (2006), Lopez-Caballero and Modaressi Farahmand-Razavi (2008), Andrianopoulos et al. (2010), Shahir and Pak (2010), Dashti and Bray (2013), Lopez-Caballero and Modaressi Farahmand-Razavi (2013), and Karamitros et al. (2013) conducted 2-D (plane strain) and 3-D, fully coupled, nonlinear, finite element and finite difference analyses to study the dynamic interaction between homogeneous and layered liquefiable sand and a structure. In these analyses, the structure was simulated either as a surface load, rigid structure, or an elastic SDOF model. The foundation was mostly

fixed to the soil mesh, assuming no relative movement at the interface.

Numerical simulations of SDOF structures on liquefiable ground have shown that liquefaction increases the building's settlement potential, but reduces the seismic demand on the structure and the peak inter-story drift ratio (Lopez-Caballero and Farahmand-Razavi 2013). This observation agrees with previous case histories and may influence the choice and design of remediation techniques in the future. Further, the characteristics of input ground motion used in numerical simulations have been shown to govern the effectiveness of the mitigation technique in terms of settlement and inter-story drift.

Structural engineers employ high-fidelity analytical models of structures, often with no consideration of soil response or soil-structure interaction. In addition, most work in numerical modeling of earthquake effects on structures has focused on the effects of ground shaking alone. Only a few studies have addressed the combined influence of shaking and liquefaction-induced permanent ground movements on the performance of a structure (e.g., Fotopoulou and Pitilakis 2012; Negulescu and Foerster 2010; Aygun et al. 2011). At this time, the influence of ground settlement on the building's engineering demand parameters and damage potential is not clearly understood for a wide range of structures, ground motions, and soil conditions. Complex, nonlinear, dynamic simulations of the soil-structure system are expensive and time consuming and often not justifiable in most projects.

In summary, most analyses of soil liquefaction have ignored structural performance and nonlinearities. On the other hand, nonlinear analyses of structures typically ignore soil nonlinearities or bring in ground shaking and permanent soil displacements in a decoupled manner. It is advantageous, if the project resources allow, that the triggering of liquefaction, post-liquefaction instability, the resulting displacements and ground shaking, and the nonlinear response of the structure be considered simultaneously in a coupled analysis. This approach brings in the complexities of both soil and structure, in order to accurately evaluate the performance of structures on

liquefied ground and the effectiveness of mitigation methods in terms of improved performance. At this time, the cost and expertise required for reliably running such analyses are often prohibitive for most projects.

Summary

The profession has largely addressed the problem of liquefaction triggering assessment. However, there is still much uncertainty in evaluating the consequences of liquefaction in terms of building settlements and the effect of those settlements on building performance. Reliable and simplified procedures for estimating liquefaction-induced building movements that take into account the key displacement mechanisms are currently lacking. As such, observations of ground and building response in the previous case histories, physical model studies, and numerical analyses are combined in this article to provide an overview of the complexities of the problem and guidance for practicing engineers.

The governing displacement mechanisms near a structure are primarily deviatoric induced when the liquefiable soil layer is sufficiently thick and shallow. Methods that estimate free-field, post-liquefaction, volumetric reconsolidation settlement (e.g., Tokimatsu and Seed 1987; Ishihara and Yoshimine 1992) cannot be used to estimate building settlement, because they cannot estimate deviatoric displacement. These procedures either completely ignore the presence of the structure or simplistically bring in its influence through an added foundation load.

It is not appropriate to normalize building settlements by the thickness of the liquefied soil layer. This type of normalization implies that volumetric-induced displacement mechanisms govern building settlement. This is not the case for shallow liquefiable layers under a building, where deviatoric displacement mechanisms dominate (ϵ_{q-BC} and ϵ_{q-SSI}). Localized volumetric strains resulting from partial drainage in response to intense transient hydraulic gradients (ϵ_{p-DR}) are also important.

If liquefaction is triggered in the free field, it is likely that it will also occur under the edges of a building's shallow foundation and in the adjacent soil (Travasrou et al. 2006; Dashti et al. 2010a, b). If significant excess pore water pressures are expected to be generated, liquefaction-induced building movements should be evaluated. A well-calibrated, fully coupled, nonlinear, effective stress dynamic analysis may be performed to provide insight into the consequences of liquefaction in terms of displacements and building performance. This type of advanced analysis may be justifiable for sensitive projects and should only be performed by well-trained and experienced engineers with calibrated and validated constitutive models.

For many regular projects, performing sophisticated, nonlinear, effective stress, dynamic analyses of the soil-structure system may not be practical. First, as an initial check, the seismic bearing capacity of the building must be evaluated taking into account the available post-liquefaction, residual strength of the foundation soil, and the inertial loading of the building. If bearing capacity failure is a concern (factor of safety of near 1), large differential building settlements are expected with a possibility of failure. Hence, remediation is necessary. If the building passes this first instability check, small to moderate settlements are expected typically, for which there are currently no reliable, simplified analytical methods available. In these cases, the available empirical methods for estimating volumetric settlement in the free field must be used with caution and engineering judgment. Considerable localized volumetric strains due to partial drainage as well as static and dynamic deviatoric strains may produce large building settlements and tilt, none of which are taken into account by the available procedures. Special attention should be given to taller buildings with higher aspect ratios (i.e., $H/B > 1.5$), which are more prone to tilting or extreme differential settlements. Previous case histories and physical model studies have shown that a building's tilting potential and overall settlements increase proportionally with its aspect ratio (i.e., H/B) and contact pressure, respectively (Sancio et al. 2004; Dashti

et al. 2010a). In designing a mitigation measure, the dominating mechanisms of displacement should be considered and minimized.

The liquefaction hazard facing existing structures in many parts of the world demands more reliable, performance-based engineering procedures to design remediation techniques. These methods should focus on reducing displacements under and around the foundation as well as structural nonlinearities. Soil, foundation, and building response need to be explicitly linked to damage in developing effective and economic remediation strategies in the future.

Liquid Storage Tanks: Seismic Analysis

Maria Vathi and Spyros A. Karamanos
Department of Mechanical Engineering,
University of Thessaly, Volos, Greece

Synonyms

Dynamic analysis of liquid storage tanks; Earthquake analysis of liquid containers

Introduction

Liquid-containing tanks are used in water distribution systems and in industrial plants for the storage and/or processing of a variety of liquids and liquid-like materials, including oil, liquefied natural gas, chemical fluids, and wastes of different forms. These tanks are mainly categorized in two types: ground-supported tanks and elevated tanks. In the present chapter, ground-supported tanks of upright cylindrical shape are presented.

As the necessity and importance of liquid storage tanks has increased over the years, mainly because of their association with the need for continuous supply of energy and water resources, so has the need to understand better their structural behavior and performance. In particular, the analysis and design of liquid storage tanks against earthquake-induced actions has been recognized as an important issue towards safeguarding their structural integrity and has been the subject of numerous analytical, numerical, and experimental works. A pioneering work of Housner (1957), motivated by the need for accurate determination of seismic actions in tanks, presented a solution for the hydrodynamic effects in non-deformable

vertical cylinders and rectangles. For the first time, the total seismic action was split in two parts, namely, the “impulsive” part and the “convective” part. This concept constitutes the basis for the American Petroleum Institute (2003, 2007) Standard provisions (Appendix E) for vertical cylindrical tanks. Veletsos and Yang (1977) and Haroun (1983) have extended this formulation to include the effects of shell deformation and its interaction with hydrodynamic effects. More recently, the case of uplifting of unanchored tanks as well as soil-structure interaction effects have been studied extensively, in the papers by Peek (1988), Natsiavas (1988), Veletsos and Tang (1990), and Malhotra (1995). Notable contributions on the seismic response of anchored and unanchored liquid storage tanks have been presented by Fischer (1979) and Rammerstorfer et al. (1988), with particular emphasis on design implications. Apparently, those papers constitute the basis for the seismic design provisions concerning vertical cylindrical tanks in Part 4 of Eurocode 8, Annex A (European Committee for Standardization 2006b). In addition to the numerous analytical/numerical works, notable experimental contributions on this subject have been reported (Niwa and Clough 1982; Manos and Clough 1982). The reader is referred to the review paper of Rammerstorfer et al. (1990) for a literature review of liquid storage tank response under seismic loads, including fluid-structure and soil-structure interaction effects. Recently, the European research project INDUSE (Pappa et al. 2012) has been completed on the seismic analysis and design of industrial facilities, with particular emphasis on liquid storage tanks. Results from this study have been incorporated in specific design guidelines.

During a strong seismic event, liquid storage tanks may exhibit significant damages. Typical tank damage can be in the following form: (a) buckling of the shell, precipitated by excessive axial compression due to overall bending or beamlike action of the structure; (b) damage to the roof, caused by sloshing of the upper part of the contained liquid when there is insufficient freeboard between the liquid surface and the roof; and (c) failure of attached piping and other

accessories, due to the inability of these elements to accommodate the deformations of the flexible shell. Shell buckling usually takes the form of “diamond shaped” or “elephant’s foot” buckling that appears at a short distance above the base and usually extends around most or all of the circumferences. In previous earthquake events, damages of various severity have been reported, e.g., from fracture of a pipe that created only slight leaks on minor repairs (damage to an overflow pipe) to complete loss of tank content.

Seismic analysis of liquid-containing tanks differs from typical civil engineering structures (i.e., buildings and bridges) in two ways: First, during seismic excitation, liquid inside the tank exerts hydrodynamic force on tank walls and base due to liquid-tank interaction. Second, liquid storage tanks are generally very thin walled and this results in relatively low ductility and low redundancy.

The present chapter outlines principles and methodologies for the seismic analysis of above-ground ground-supported liquid storage tanks of upright cylindrical shape without restrictions on their size and their use. The contents of this chapter are applicable to tanks for both hydrocarbon (oil) and water storage. However, they do not cover containers of different shape, such as horizontal-cylindrical and spherical vessels. For the seismic design of such vessels, the reader is referred to the publication of Karamanos et al. (2006). In addition, they do not refer to elevated tanks, where the tank is supported on braced or unbraced legs, on skirt, or on a more complex structural system. Moreover, the present chapter refers mainly to steel tanks, which are widely used in industrial applications. However, the basic principles of this chapter can be applicable to tanks made of different material.

In the present chapter, following a short presentation of current design standards in “[Relevant Standards and Guidelines](#)”, and a short reference to the seismic input in the course of spectral analysis in “[Seismic Input](#)”, seismic actions in liquid storage tanks are discussed in “[Seismic Loading on Liquid Storage Tanks](#)” in a concise manner, with special reference to hydrodynamic loading. In “[Special Issues on Seismic Action](#)”,

some special issues including the response of unanchored tanks are discussed, whereas in “[Seismic Resistance of Liquid Storage Tanks](#)”, the resistance of liquid storage tanks is outlined. Finally, in “[Summary](#)”, some concluding remarks are stated.

Relevant Standards and Guidelines

There exist several relevant standards and guidelines for the seismic analysis of liquid storage tanks. In this paragraph, the most important European and American Standards as well as the New Zealand Recommendations (Priestley et al. [1986](#)) are briefly presented.

A basic standard on tank seismic design is the 4th part of Eurocode 8 (European Committee for Standardization [2006b](#)). It is a standard that concerns the seismic design of silos, tanks, and pipelines for earthquake resistance and is part of the CEN/TC250 standard group, often referred to as “Structural Eurocodes.” It specifies principles and application rules for the seismic design of structural components including aboveground and buried pipeline systems, silos, and storage tanks of different types and uses. This standard contains significant information on the calculation of seismic action based mainly on the work of Scharf ([1990](#)). Furthermore, seismic resistance in terms of shell buckling is based mainly on the work of Rotter ([1990](#)). It should be noted that EN 1998-4 rules are quite general and may refer to tanks of different material, i.e., steel, concrete, or plastic. It should be noted that this standard should be used together with the other relevant Structural Eurocodes. More specifically, Part 1 of Eurocode 8 (European Committee for Standardization [2004a](#)) should be used for the seismic input in terms of the design spectrum. In addition, Part 1–6 of Eurocode 3 (European Committee for Standardization [2007](#)) gives basic design rules for the strength and structural stability of steel tanks, covering the basic failure modes of steel shells, namely, plasticity, cyclic plasticity, buckling, and fatigue, with emphasis on buckling. Finally, Part 4.2 of Eurocode 3 (European Committee for Standardization

[2006a](#)) provides principles and application rules for the general structural design of vertical cylindrical aboveground steel tanks for the storage of liquid products that should be taken into account.

API 650 (American Petroleum Institute [2007](#)) is a standard dedicated to the general design of liquid storage tanks, developed by the American Petroleum Institute and widely used by the petrochemical industry for the design and construction of tanks in petrochemical facilities. In particular, Appendix E of API 650 refers exclusively to seismic design and contains provisions for both determining seismic actions on tanks and calculating the strength of the tank. Appendix E of the new 11th edition of API 650 (American Petroleum Institute [2007](#)) has significant revisions with respect to the previous 2003 edition (American Petroleum Institute [2003](#)) and includes provisions for site-specific seismic input, calculation of hoop hydrodynamic stresses, distinction between ringwall and slab overturning moments, freeboard requirements, and consideration of vertical excitation effects. It should be noted that the seismic provisions of the updated Appendix E are in accordance with the provisions of ASCE 7 Standard (American Society of Civil Engineers [2006](#)), which refers to structural loading.

EN 14015 (European Committee for Standardization [2004b](#)) is a European standard outside the Structural Eurocode framework, i.e., independent of EN 199x Standards, which specifies the requirements for the materials, design, fabrication, erection, testing, and inspection of site built, vertical, cylindrical, flat-bottomed, aboveground, welded, steel tanks for the storage of liquids at ambient temperatures and above. It constitutes an updated version of the classical British Standard BS 2654 (British Standards Institution [1989](#)), which is a specification for the manufacture of vertical steel welded non-refrigerated storage tanks with butt-welded shells for the petroleum industry. It is a complete standard for tank design analogous to API 650 (American Petroleum Institute [2007](#)). Recommendations for seismic design and analysis of storage tanks are stated in Annex G of EN 14015,

which are quite similar with the requirements of Annex E of API 650 (American Petroleum Institute 2003).

The New Zealand Seismic Tank Design Recommendations (Priestley et al. 1986) is a document that, when published in 1986, contained pioneering recommendations for the seismic design of storage tanks, developed by a study group of the New Zealand National Society for Earthquake Engineering. The intention of this study group was to collate existing information, available in research papers and codes, and to produce uniform recommendations that would cover a wide range of tank configurations and contained materials. These recommendations attempted to produce a unified approach for the seismic design of storage tanks, regardless of material or function, and to provide additional information to that already available in alternative sources. Several decades after their publication, these recommendations have been widely referenced and adopted internationally, including EN 1998-4 (European Committee for Standardization 2006b).

Seismic Input

In the framework of a pseudo-dynamic spectral analysis, the earthquake motion is represented by an appropriate design spectrum, $S_a(T)$. As an example, EN 1998-1 (European Committee for Standardization 2004a) provides a design spectrum for general use. Similar design spectra are provided by all seismic design codes. The design spectrum for horizontal earthquake excitation is usually expressed through an analytical equation for the spectral acceleration S_a in terms of the natural period T of the structural system, the design ground acceleration a_g , the damping coefficient ξ , the behavior factor q , the importance factor γ_I , and the soil factor S .

In addition, provisions for the vertical component of the seismic action are given in terms of the peak vertical ground acceleration a_{gv} usually as a percentage of a_g . In this section, two main issues, the behavior factor and the importance factor, are discussed in more detail.

Behavior Factor

The behavior factor, q , accounts for the capacity of the structural system to dissipate seismic energy. This results in a reduction of the forces obtained from a linear elastic analysis, in order to account for the nonlinear response of the structure, associated with the material, the structural system, and the design procedure. However, the structural system should be able to sustain such nonelastic behavior and dissipate seismic energy.

Upright cylindrical steel tanks (non-base-isolated) supported directly on the ground or on the foundation may be designed with a behavior factor q that represents a quasi-elastic behavior, i.e., $q \leq 1.5$. More specifically, a value of $q = 1$ is recommended for the convective motion where negligible dissipation of energy occurs, whereas a value of $q = 1.5$ (quasi-elastic behavior) is recommended for the impulsive motion.

The relatively low values of q for the impulsive motion are justified by the unstable nature of shell buckling primary mode of failure. This philosophy is adopted by European Standard EN 1998-4 (European Committee for Standardization 2006b). According to this standard, values of behavior factor greater than 1.5 for the impulsive motion can be used (up to 2.5); in special cases when the tank or its foundation is appropriately designed to allow uplift and the localization of deformations in the shell wall, the bottom plate or their intersection does not cause failure.

American Standard API 650 (American Petroleum Institute 2007) uses a similar concept to account for the capacity of the tank to dissipate seismic energy through the so-called response modification factor or simply reduction factor, denoted by “ R .” The response modification factor for ground-supported, liquid storage tanks designed and detailed to these provisions shall be less than or equal to the values shown in Table E-4 of API 650.

Nevertheless, there exist significant differences between API 650 (American Petroleum Institute 2007) and EN 1998-4 (European Committee for Standardization 2006b) for the value of the behavior factor. In particular, API

650 proposes larger values for the behavior factor for both the impulsive and convective actions than EN 1998-4. It is important to note that in both standards those values are significantly higher than unity which implies the presence of a dissipating mechanism.

In conclusion, the behavior (reduction) factor for the seismic design of liquid storage tanks is a controversial issue that has not been examined thoroughly so far.

Importance Factor

Reliability differentiation in liquid storage tank design is implemented by classifying tanks into different “importance classes.” The importance classes depend on the potential loss of life due to the failure of the particular tank and on the economic and social consequences of failure. Clearly, the importance of a specific tank should be assessed considering the facility or plant it belongs to and its proximity to urban areas. In EN 1998-4 (European Committee for Standardization 2006b), the following classes for liquid storage tanks are specified:

- *Class I* refers to situations where the risk to life is low and the economic and social consequences of failure are small or negligible.
- Situations with medium risk to life and local economic or social consequences of failure belong to *Class II*.
- *Class III* refers to situations with a high risk to life and large economic and social consequences of failure.
- *Class IV* refers to situations with exceptional risk to life and extreme economic and social consequences of failure.

An importance factor γ_I is assigned to each importance class, ranging from 0.8 to 1.6 for the four importance classes unless otherwise specified in National Annexes, depending on the local seismic hazard conditions or by the owner. An analogous classification (with three important classes) is also specified in API 650 (American Petroleum Institute 2007), Appendix E, Section E.5.1.2, Table E-5.

Seismic Loading on Liquid Storage Tanks

Horizontal Seismic Action

General

A cylindrical coordinate system is usually used to describe the tank geometry with orthogonal coordinates: r, φ, z where the origin at the centre of the tank bottom and the z axis is vertical (Fig. 1). The height of the tank to the original of the free surface of the fluid and its radius are denoted by H and R , respectively; ρ is the mass density of the fluid, while the nondimensional coordinates $\xi = r/R$ and $\zeta = z/H$ in the radial direction and along the height of the tank, respectively, are usually considered.

The liquid contained in an upright cylinder subjected to horizontal seismic excitation $\ddot{X}(t)$ may be considered as ideal fluid (potential flow) resulting in a hydrodynamic problem (Ibrahim 2005) associated with the motion of the liquid free surface and the development of standing waves. The solution of the hydrodynamic problem shows that the liquid motion can be expressed as the sum of two separate contributions, called impulsive and convective, respectively. The impulsive component of the motion satisfies exactly the boundary conditions at the tank wall and the bottom of the tank and corresponds to zero pressure at the free surface of the fluid. It represents the motion of the fluid part that “follows” the motion of the container. The convective term is associated with liquid sloshing of

Liquid Storage Tanks: Seismic Analysis, Fig. 1 Cylindrical coordinate system describing tank geometry

its free surface and satisfies the kinematic and dynamic conditions at the free surface.

As a result, the hydrodynamic pressure is decomposed into an impulsive part and a convective part. In an analogous manner, the total mass of the liquid, m_L , can be considered as the sum of two parts, an impulsive part, m_I , and a convective part, m_C , so that $m_L = m_I + m_C$.

The convective motion is associated with an infinite number of modes and the corresponding masses are computed as follows:

$$\frac{m_{Cn}}{m_L} = \frac{2 \tanh(k_n R \gamma)}{k_n R \gamma (k_n^2 R^2 - 1)}, \quad n = 1, 2, 3, \dots \quad (1)$$

where n is the number of sloshing mode, R is the radius of the tank, γ is the tank aspect ratio defined as the ratio of the liquid height over the tank radius ($= H/R$), and $k_n R = \lambda_n$ are the roots of equation $J'_1(\cdot) = 0$. More specifically the first three roots are $k_1 R = \lambda_1 = 1.841$, $k_2 R = \lambda_2 = 5.331$, and $k_3 R = \lambda_3 = 8.536$ corresponding to the first three sloshing modes. Note that the total convective mass is the sum of the individual convective masses, $m_C = \sum_{n=1}^{\infty} m_{Cn}$. Usually, consideration of only the first one ($n = 1$), or the first two modes ($n = 1, 2$) in some special cases, is adequate for design purposes.

Masses m_I and m_{Cn} for $n = 1, 2$ are plotted in Fig. 2 as functions of the tank aspect ratio $\gamma = H/R$. The impulsive mass is expressed as the ratio m_I/m_L of the impulsive mass over the total liquid mass. This ratio increases with

increasing values of γ , tending asymptotically to unity. On the other hand, the convective mass, expressed in normalized form as m_{C1}/m_L , decreases with increasing values of γ . The value of m_{C2} is quite small but may have some effect on the dynamic response in broad tanks where $\gamma \rightarrow 0$.

In the course of a design procedure, the impulsive mass m_I should consist of the above impulsive mass of the liquid, plus the mass of the moving tank wall, m_{SH} , and the mass of the tank roof, m_r .

Vibration Periods and Damping Coefficients

In case of rigid (non-deformable) tank walls, the impulsive motion follows exactly the ground motion. In such a case the impulsive circular frequency has an infinite value ($\omega_I \rightarrow \infty$) and the impulsive period is zero ($T_I = 0$). This is not applicable in the case of flexible (deformable) tank walls. To simplify the analysis, it is reasonable to assume that the flexibility of tank wall affects almost exclusively the impulsive component of the response, and therefore, the impulsive hydrodynamic effects for flexible tanks are generally significantly larger than those for rigid tanks. On the other hand, the convective components of the response can be considered insensitive to variations in wall flexibility, because they are associated with natural periods of vibration that are significantly longer than the dominant periods of the ground motion or pipe wall vibration motion. Therefore, the convective components of seismic action for tank proportions normally encountered in practice can be

Liquid Storage Tanks: Seismic Analysis,

Fig. 2 Mass ratio as a function of the aspect ratio

considered the same as those obtained for rigid tanks.

Analytical expressions are available for the impulsive vibration period and frequency accounting for tank flexibility. From hydrodynamics, the natural circular frequency and natural period of the impulsive response of flexible tanks are calculated by the expressions:

$$\omega_I = \frac{2\pi}{Y_I H \sqrt{\frac{\rho R}{t_{eq} E}}} \quad (2)$$

$$T_I = Y_I H \sqrt{\frac{\rho R}{t_{eq} E}} \quad (3)$$

where ρ is the mass density of the fluid, E is Young's modulus, t_{eq} is the equivalent uniform thickness of the tank wall (can be taken as the weighted average over the wetted height of the tank wall, the weight may be taken proportional to the strain in the wall of the tank, which is maximum at the base of the tank), and coefficient Y_I is given in Table 1 for specific values of the aspect ratio γ of the tank ($\gamma = H/R$). For intermediate values of γ , a simple interpolation may be used.

Furthermore, the circular frequency (Fig. 3) and natural period of the convective response,

denoted as ω_{Cn} and T_{Cn} , respectively, for the n -th sloshing mode can be calculated by the following expressions:

$$\omega_{Cn} = \sqrt{g \frac{\lambda_n}{R} \tanh(\lambda_n \gamma)}, \quad n = 1, 2, 3, \dots \quad (4)$$

$$T_{Cn} = \frac{2\pi}{\omega_{Cn}}, \quad n = 1, 2, 3, \dots \quad (5)$$

where λ_n are the roots of $J'_1(\cdot) = 0$, $\lambda_1 = 1.841$, $\lambda_2 = 5.331$, and $\lambda_3 = 8.536$ for the first three sloshing modes).

The impulsive and convective damping coefficients can be taken equal to $\xi_I = 5\%$ and $\xi_C = 0.5\%$ for the impulsive and the convective motion, respectively.

Impulsive Motion and Pressure

The impulsive motion can be expressed in terms of the impulsive acceleration of the liquid storage tank, $\ddot{u}_I(t)$, which can be calculated from the following linear oscillator equation:

$$\ddot{u}_I + 2\xi_I \omega_I (\dot{u}_I - \dot{X}) + \omega_I^2 (u_I - X) = 0 \quad (6)$$

where $u_I(t)$ is the generalized coordinate representing the total impulsive displacement

Liquid Storage Tanks: Seismic Analysis, Table 1 Coefficient Y_I in terms of the aspect ratio

H/R	0.3	0.5	0.7	1.0	1.5	2.0	2.5	3.0
Y_I	9.28	7.74	6.97	6.36	6.06	6.21	6.56	7.03

Liquid Storage Tanks: Seismic Analysis,

Fig. 3 Values of the first two sloshing frequencies as functions of γ

motion of the tank, ξ_I the viscous damping ratio of the impulsive motion, and ω_I the impulsive frequency defined in Eq. 2. Setting

$$a_I(t) = u_I(t) - X \quad (7)$$

one can obtain

$$\ddot{a}_I + 2\xi_I\omega_I\dot{a}_I + \omega_I^2 a_I = -\ddot{X}(t) \quad (8)$$

In the above expressions, function $a_I(t)$ can be considered as the generalized coordinate representing the relative impulsive displacement of the tank with respect to its base.

The spatial-time variation of the *impulsive* component of hydrodynamic pressure within the liquid domain is given by the following expression:

$$p_I(\xi, \zeta, \varphi, t) = C_I(\xi, \zeta) \rho H \cos \varphi \ddot{u}_I(t) \quad (9)$$

where the spatial coefficient C_I is defined:

$$C_I(\xi, \zeta) = 2 \sum_{n=0}^{\infty} \frac{(-1)^n}{I_1'(v_n/\gamma) v_n^2} \cos(v_n \zeta) I_1\left(\frac{v_n}{\gamma} \xi\right) \quad (10)$$

in which $v_n = \frac{2n+1}{2}\pi$, $\gamma = H/R$ is the aspect ratio of the tank, whereas $I_1(\cdot)$ and $I_1'(\cdot)$ denote the modified Bessel function of order 1 and its derivative, respectively.

For seismic design purposes, the distribution of the impulsive hydrodynamic pressure on the pipe walls is assumed as follows:

$$p_I(\xi, \zeta, \varphi) = C_I(\xi, \zeta) \rho H \cos \varphi S_a(T_I) \quad (11)$$

where ξ is taken equal to 1 for computing the pressure on the lateral surface of tank shell, whereas ζ should be considered equal to zero for calculating the pressure on the tank bottom plate (Fig. 4).

Liquid Storage Tanks: Seismic Analysis,

Convective Motion and Pressure

The convective acceleration, $\ddot{u}_{Cn}(t)$, is calculated from the following linear oscillator equation:

$$\ddot{u}_{Cn} + 2\xi_{Cn}\omega_{Cn}(\dot{u}_{Cn} - \dot{X}) + \omega_{Cn}^2(u_{Cn} - X) = 0 \quad (12)$$

where $u_{Cn}(t)$ is the generalized coordinate representing the total convective motion of the liquid associated with the n -th mode, ξ_{Cn} the viscous damping ratio of the convective motion for the n -th sloshing mode, and ω_{Cn} the convective frequency. Setting

$$a_{Cn}(t) = u_{Cn}(t) - X \quad (13)$$

one can write

$$\ddot{a}_{Cn} + 2\xi_{Cn}\omega_{Cn}\dot{a}_{Cn} + \omega_{Cn}^2 a_{Cn} = -\ddot{X}(t) \quad (14)$$

where $a_{Cn}(t)$ is the generalized coordinate representing the relative convective motion of the liquid associated with the n -th sloshing mode.

The spatial distribution within the liquid domain and time variation of the “convective” component of hydrodynamic pressure associated with the n -th convective mode is given by the following expression:

$$p_{Cn}(\xi, \zeta, \varphi, t) = \rho\psi_n \cosh(\lambda_n \gamma \zeta) J_1(\lambda_n \xi) \cos \varphi \ddot{u}_{Cn}(t) \quad (15)$$

where

$$\psi_n = \frac{2R}{(\lambda_n^2 - 1)J_1(\lambda_n) \cosh(\lambda_n \gamma)} \quad (16)$$

J_1 is the Bessel function of the first order and $\lambda_1 = 1.841$, $\lambda_2 = 5.331$, and $\lambda_3 = 8.536$ are the roots of $J_1'(\lambda) = 0$. In Eq. 15, r is taken equal to $R(\xi = 1)$ for the pressure on the lateral surface, whereas z is taken equal to zero ($\zeta = 0$) for the pressure on the bottom plate. In the majority of practical applications, only the first convective mode ($n = 1$) of the fluid is necessary (Pappa et al. 2011) and the distribution of the pressure is as follows:

$$p_C(\xi, \zeta, \varphi) = 1.146R\rho \frac{\cosh(1.841\gamma\zeta)J_1(1.841\xi)}{\cosh(1.841\gamma)} \cos \varphi S_a(T_{C1}) \quad (17)$$

where J_1 is the Bessel function of first order. In the above expressions, r is taken equal to R ($\xi=1$) for determining the hydrodynamic pressure on the lateral tank (shell) surface (Fig. 5),

whereas z is taken equal to zero ($\zeta = 0$) for the hydrodynamic pressure on the bottom plate. In addition, 1.841 is the first root of $J_1'(0) = 0$.

Liquid Storage Tanks: Seismic Analysis,

Fig. 5 Variation of first-mode sloshing pressures on tank wall along the tank height

Liquid Storage Tanks: Seismic Analysis,
Fig. 6 Horizontal seismic force Q acting at a height h

In broad tanks (i.e., tanks with large values of H/R ratio), the sloshing pressures may be significant near the bottom, while in slender (tall) tanks, the sloshing effect is limited to the vicinity of liquid surface.

Horizontal Seismic Forces

Integrating the pressure distribution on the tank wall, the impulsive base shear force at the base of the wall can be calculated as follows:

$$Q_I(t) = \int_{B_q} p_I(\mathbf{n} \cdot \mathbf{e}_x) dB_q \quad (18)$$

where $\mathbf{e}_x$ is the unit vector in the direction of the earthquake, $\mathbf{n}$ is the unit normal vector to the liquid surface, and B_q is the boundary surface of the liquid (Fig. 6).

The result of this integration can be readily written as follows:

$$Q_I(t) = m_I \ddot{u}_I(t) \quad (19)$$

where m_I is the impulsive mass defined in Fig. 2 and $\ddot{u}_I(t)$ is the impulsive acceleration parameter, defined in Eq. 6.

The convective base shear can be obtained by integrating the convective pressure (p_C) components on the lateral shell of the tank:

$$Q_C(t) = \int_{B_q} p_C(\mathbf{n} \cdot \mathbf{e}_x) dB_q \quad (20)$$

The result of this integration can be readily written as follows:

$$Q_C(t) = \sum_{n=1}^{\infty} m_{Cn} \ddot{u}_{Cn}(t) \quad (21)$$

where m_{Cn} is the convective mass for the n -th mode defined in Fig. 2 and $\ddot{u}_{Cn}(t)$ is the convective acceleration parameter for the n -th sloshing mode, defined in Eq. 12.

In the course of a spectral seismic analysis of the tank, the impulsive base shear Q_I and convective base shear Q_{Cn} for the n -th mode at the base of the wall can be computed in terms of the corresponding spectral acceleration as follows:

$$Q_I = m_I S_a(T_I) \quad (22)$$

$$Q_{Cn} = m_{Cn} S_a(T_{Cn}), \quad n = 1, 2, 3, \dots \quad (23)$$

Ringwall and Slab Overturning Moment/Heights

The ringwall moment, M , is the overturning moment that acts immediately above the bottom plate of the tank. It includes only the contribution of pressure on the wall and should be used for the calculation of stresses and stress resultants in the tank wall and at its connection to the base, for tank structural verification. On the other hand, the slab moment, M' , is the overturning moment that acts immediately below the bottom plate of the tank. It includes the contribution of pressure on the wall together with the pressure on the tank bottom and should be used for the verification of its support structure, base anchors, or foundation.

The impulsive ringwall base moment is calculated through the following integration:

$$M_I(t) = \int_{B_q} p_I z(\mathbf{n} \cdot \mathbf{e}_x) dB_q \quad (24)$$

The result of this integration can be readily written as follows:

$$M_I(t) = m_I h_I \ddot{u}_I(t) \quad (25)$$

or

$$M_I(t) = Q_I(t) h_I \quad (26)$$

where m_I is the impulsive mass defined in Fig. 2; h_I is the height at which acts the horizontal seismic force, $Q_I(t)$; and $\ddot{u}_I(t)$ is the impulsive acceleration parameter, defined in Eq. 6.

The convective ringwall base moment is calculated in an analogous manner:

$$M_C(t) = \int_{B_q} p_{Cz}(\mathbf{n} \cdot \mathbf{e}_x) dB_q \quad (27)$$

The result of this integration can be readily written as follows:

$$\begin{aligned} M_C(t) &= \sum_{n=1}^{\infty} m_{Cn} \ddot{u}_{Cn}(t) h_{Cn} \\ &= \sum_{n=1}^{\infty} Q_{Cn}(t) h_{Cn} \end{aligned} \quad (28)$$

where m_{Cn} is the convective mass for the n -th mode defined in Fig. 2; h_{Cn} is the height at which acts the horizontal seismic force for the n -th sloshing mode, $Q_{Cn}(t)$; and $\ddot{u}_{Cn}(t)$ is the

convective acceleration parameter for the n -th sloshing mode, defined in Eq. 12.

Analytical expressions for the heights at which impulsive and convective forces are acting are available from hydrodynamics, represented also in graphical form in Fig. 7.

For the impulsive moment:

$$h_I = H \frac{\sum_{n=0}^{\infty} \frac{(-1)^n I_1(v_n/\gamma)}{v_n^4 I_1'(v_n/\gamma)} (v_n(-1)^n - 1)}{\sum_{n=0}^{\infty} \frac{I_1(v_n/\gamma)}{v_n^3 I_1'(v_n/\gamma)}} \quad (29)$$

$$h'_I = H \frac{\frac{1}{2} + 2\gamma \sum_{n=0}^{\infty} \frac{v_n + 2(-1)^{n+1} I_1(v_n/\gamma)}{v_n^4 I_1'(v_n/\gamma)}}{2\gamma \sum_{n=0}^{\infty} \frac{I_1(v_n/\gamma)}{v_n^3 I_1'(v_n/\gamma)}} \quad (30)$$

For the convective moment:

$$h_{Cn} = H \left(1 + \frac{1 - \cosh(\lambda_n \gamma)}{\lambda_n \gamma \sinh(\lambda_n \gamma)} \right) \quad (31)$$

Liquid Storage Tanks: Seismic Analysis,

Fig. 7 Ratios h_I/H , h'_I/H , h_C/H , and h'_C/H as functions of the aspect ratio

$$h'_{Cn} = H \left(1 + \frac{2 - \cosh(\lambda_n \gamma)}{\lambda_n \gamma \sinh(\lambda_n \gamma)} \right) \quad (32)$$

In the course of a spectral design and analysis procedure, the impulsive and convective ringwall moments are given by the following expressions:

$$M_I = m_I h_I S_a(T_I) \quad (33)$$

$$M_C = m_{Cn} h_C S_a(T_{Cn}) \quad (34)$$

Furthermore, simplified equations for the height h_I are stated in Section 6.1.2 of API 650 (American Petroleum Institute 2007) as alternative to Eq. 29:

when $D/H \geq 1.333$:

$$h_I = 0.375H \quad (35)$$

when $D/H < 1.333$:

$$h_I = \left[0.5 - 0.094 \frac{D}{H} \right] H \quad (36)$$

and

$$h_C = \left[1 - \frac{\cosh\left(\frac{3.67H}{D}\right) - 1}{\frac{3.67H}{D} \sinh\left(\frac{3.67H}{D}\right)} \right] H \quad (37)$$

Similarly, the impulsive and convective slab moments are given by the following expressions:

$$M'_I = m_I h'_I S_a(T_I) \quad (38)$$

$$M'_C = m_{Cn} h'_C S_a(T_{Cn}) \quad (39)$$

and an alternative equation for the height h'_I can be found in Section 6.1.2 of API 650 (American Petroleum Institute 2007):

when $D/H \geq 1.333$:

$$h'_I = 0.375 \left[1 + 1.333 \left(\frac{0.866 \frac{D}{H}}{\tanh\left(0.866 \frac{D}{H}\right)} - 1 \right) \right] H \quad (40)$$

when $D/H < 1.333$:

$$h'_I = \left[0.5 - 0.06 \frac{D}{H} \right] H \quad (41)$$

Combination of Impulsive/Convective Action

In the course of a spectral analysis and design procedure, the impulsive and convective action should be combined in order to compute the total horizontal hydrodynamic force. In particular it is necessary to combine (a) the sloshing modes to obtain the resultant convective action and (b) the impulsive and convective actions for the total seismic force.

Both combinations should be conducted according to the SRSS rule, rather than the addition of the maximum convective and maximum impulsive forces as noted in a recent publication (Pappa et al. 2011).

More specifically, the total horizontal seismic force is

$$Q_T = \sqrt{[m_I S_a(T_I)]^2 + \sum_{n=1}^{N_1} [m_{Cn} S_a(T_{Cn})]^2} \quad (42)$$

where N_1 is the number of sloshing modes considered.

The above SRSS combination rule applies also to the total “ringwall” and “slab” moments:

$$M_T = \sqrt{[m_I h_I S_a(T_I)]^2 + \sum_{n=1}^{\infty} [m_{Cn} h_C S_a(T_{Cn})]^2} \quad (43)$$

$$M'_T = \sqrt{[m_I h'_I S_a(T_I)]^2 + \sum_{n=1}^{\infty} [m_{Cn} h'_C S_a(T_{Cn})]^2} \quad (44)$$

One should note that the impulsive force is significantly higher than the convective force. Therefore, in most of the cases, refinements on the value of the convective force and the combination of the corresponding modes are of little importance on the calculation of the total seismic force (Pappa et al. 2011).

Meridional Stresses

The meridional stress, σ_z , in mechanically anchored tanks is related to meridional membrane force, N , per unit circumferential length:

$$\sigma_z = N/t_i \quad (45)$$

where t_i is the thickness of the tank shell course under consideration and the axial force N per unit circumferential length is given by the following equations:

- On the compression side of the tank (Fig. 8 – location 1):

$$N = -1.273 \frac{M_T}{D^2} - w_t(1 + cA_v) \quad (46)$$

- On the tension side of the tank (Fig. 8 – location 2):

$$N = 1.273 \frac{M_T}{D^2} - w_t(1 - cA_v) \quad (47)$$

where A_v is the spectral acceleration coefficient for the vertical motion in [% g] ($A_v = 100a_{gv}/g$), w_t is the load per unit circumferential length because of shell and roof weight acting at the base of shell [N/m] calculated by

$$w_t = \frac{W_s}{\pi D} + w_{rs} \quad (48)$$

and c is a factor that reflects the contribution of the vertical component. In Eq. 48 W_s is the total weight of the tank shell and appurtenances and w_{rs} is the load acting on the shell roof. Note that

the first term in Eqs. 46 and 47 is directly obtained from simple mechanics of materials considering bending stresses of a beam of circular cross section.

In API 650 (American Petroleum Institute 2007), the value of c is taken equal to 0.40, whereas EN 1998-4 (European Committee for Standardization 2006b) does not give an explicit expression for the effect of the vertical ground acceleration component on the meridional stresses.

Hoop Hydrodynamic Stresses

In the course of seismic loading, the hydrodynamic pressure loading on the tank wall, apart from the development of significant meridional stresses, results also in the development of additional stresses in the circumferential direction, denoted as σ_h , called hoop hydrodynamic stresses (Fig. 9).

Explicit equations for computing hoop hydrodynamic stresses for the convective and impulsive component of liquid motion (denoted as σ_{hc} and σ_{hl} respectively), in terms of the z coordinate of the tank and the D/H (aspect) ratio of the tank, are reported by Wozniak and Mitchell (1978), also adopted by API 650 (American Petroleum Institute 2007), Appendix E, Section E.6.1.4, as follows:

For tanks with $D/H \geq 1.333$:

$$\sigma_{hl} = \frac{8.48A_fGDH}{t_i} \left[\frac{z_1}{H} - 0.5 \left(\frac{z_1}{H} \right)^2 \right] \tanh \left(0.866 \frac{D}{H} \right) \quad (49)$$

For tanks with $D/H < 1.33$ and $z_1 < 0.75D$:

Liquid Storage Tanks:

Seismic Analysis,

Fig. 8 Meridional stresses σ_z on the tension side (location 1) and the compression side (location 2) of the tank under seismic loading

Liquid Storage Tanks: Seismic Analysis,

Fig. 9 Hoop hydrodynamic stresses σ_h

$$\sigma_{hl} = \frac{5.22A_I G D^2}{t_i} \left[\frac{z_1}{0.75D} - 0.5 \left(\frac{z_1}{0.75D} \right)^2 \right] \quad (50)$$

For tanks with $D/H < 1.33$ and $z_1 \geq 0.75D$:

$$\sigma_{hl} = \frac{2.6A_I G D^2}{t_i} \quad (51)$$

For all proportions of D/H :

$$\sigma_{hc} = \frac{1.85A_C G D^2 \cosh \left[\frac{3.68(H - z_1)}{D} \right]}{t_i \cosh \left[\frac{3.68H}{D} \right]} \quad (52)$$

In the above equations, stresses are expressed in [MPa], D is the nominal tank diameter in [m], H is the maximum design product level in [m], t_i is the thickness of the shell ring under consideration in [mm], $z_1 = H - z$ is the distance from the liquid surface in [m], G is the specific gravity of tank contents, and A_I and A_C are the impulsive and convective spectral acceleration coefficients in [% g] defined as $A_I = 100S_a(T_I)/g$ and $A_C = 100S_a(T_C)/g$.

The hoop stresses due to impulsive and convective motion should be combined, using the SRSS rule, and superimposed to the hydrostatic stress σ_{hs} to obtain the total hoop stress as follows:

$$\sigma_h = \sigma_{hs} + \sqrt{\sigma_{hl}^2 + \sigma_{hc}^2} \quad (53)$$

where σ_h is the total hoop stress in the shell, to be used for hoop strength design.

When vertical acceleration is taken into account, the above equation is written as follows:

$$\sigma_h = \sigma_{hs} + \sqrt{\sigma_{hl}^2 + \sigma_{hc}^2 + (A_v \sigma_{hs})^2} \quad (54)$$

where A_v is the spectral acceleration coefficient for the vertical motion in [% g].

Sloshing Wave Height

From hydrodynamics, the elevation of the liquid free surface (sloshing wave height) is given by the following expression:

$$\eta(r, \theta, t) = \sum_{n=1,2,3,\dots}^{\infty} \frac{2\lambda_n R J_1(\lambda_n \xi) \tanh(\lambda_n \gamma) \cos \theta a_{Cn}}{J_1(\lambda_n)(\lambda_n^2 - 1)} \quad (55)$$

In this expression, $\lambda_1 = 1.841$, $\lambda_2 = 5.331$, and $\lambda_3 = 8.536$ are the roots of $J'_1(\lambda) = 0$, and a_{Cn} are the generalized coordinates of the convective motion with respect to the tank base given by Eq. 14. Considering only 1 term ($n = 1$), $r = R$, one obtains Eq. 56 for the maximum elevation $\eta_{\max}$:

$$\eta_{\max} = 0.84RS_a(T_C)/g \quad (56)$$

that can be used for design purposes.

Vertical Seismic Action

The hydrodynamic pressure on the walls of a rigid tank due to vertical ground acceleration $A_v(t)$ can be computed by the following equation:

$$p_v(\zeta, t) = \rho H(1 - \zeta) \ddot{X}_v(t) \quad (57)$$

where $\ddot{X}_v(t)$ is the vertical ground acceleration input.

The corresponding hydrodynamic pressure distribution is axisymmetric and does not produce a shear force or moment resultant at any horizontal level of the tank or immediately above or below the base.

In the course of a spectral dynamic analysis, the peak vertical ground acceleration a_{gv} can be used for the calculation of p_v in the above equation replacing $\ddot{X}_v(t)$.

If one assumes that the tank is not moving rigidly with vertical acceleration $\ddot{X}_v(t)$, it may be reasonable to assume a contribution to the hydrodynamic pressure, $p_{vf}(\zeta, t)$, due to the deformability (radial “breathing”) of the shell as suggested by Fischer and Seeber (1988). This additional term may be calculated as

$$p_{vf}(\zeta, t) = 0.815f(\gamma)\rho H \cos\left(\frac{\pi}{2}\zeta\right)a_{vf}(t) \quad (58)$$

where

$$f(\gamma) = 1.078 + 0.274\ln\gamma \quad \text{for } 0.8 \leq \gamma < 4 \quad (59)$$

$$f(\gamma) = 1.0 \quad \text{for } \gamma < 0.8 \quad (60)$$

and $a_{vf}(t)$ is the acceleration response of a simple oscillator having a frequency equal to the fundamental frequency ω_{vd} of the axisymmetric vibration of the tank containing with the liquid. This fundamental frequency ω_{vd} can be calculated by the corresponding fundamental period, estimated by the expression

$$T_{vd} = 4R \left[\frac{\pi\rho H(1 - \gamma^2)I_0(\gamma_1)}{2EI_1(\gamma_1)t_{eq}} \right]^{1/2} \quad (\text{for } \zeta = 1/3) \quad (61)$$

where $\gamma_1 = \frac{\pi}{2\gamma}$ and $I_0(\cdot)$, $I_1(\cdot)$ denote the modified Bessel function of order 0 and 1, respectively. In the course of a spectral dynamic analysis, the maximum value of $a_{vf}(t)$ is obtained from the vertical acceleration response spectrum for the appropriate values of period and damping. If soil flexibility is neglected, the applicable

damping values are those of the material of the shell. Furthermore, the behavior factor value, q , adopted for the response due to the impulsive component of the pressure and the tank wall inertia may be used for the response to the vertical component of the seismic action. The maximum value of the pressure due to the combined effect of p_v and p_{vf} may be obtained by applying the SRSS combination rule to the individual maxima.

Special Issues on Seismic Action

Unanchored Tanks

Numerous aboveground tanks are not anchored to the foundation and, therefore, in the course of a strong earthquake event, uplift of tank bottom from the ground may occur due to seismic overturning moment. Uplift may cause significant plastic deformations in the tank, especially in its base plate or in the area of nozzles and piping attachments, leading to shell wall fracture and leakage of the liquid.

Base plate uplifting in those tanks referred to as unanchored or self-anchored, apart from its effect on the base plate connection may lead to an increase of the compressive vertical stress in the shell, which is critical for buckling-related modes of failure. At the wall side opposite to the uplifted area, vertical compression is maximum and hoop compressive stresses are generated in the shell, due to the membrane action of the base plate. The uplifting parameters of the tank can be seen in (Fig. 10).

The vertical uplift of two tanks with aspect ratios $\gamma = 1.131$ and 0.783 at the edge of the tank base, w , derived from a nonlinear finite element model, is given in Fig. 11 as a function of the normalized overturning moment M/WH (Vathi and Karamanos 2014).

API 650 (American Petroleum Institute 2007) provisions for tank uplifting effects are based on the value of the anchorage ratio J , defined as follows:

$$J = \frac{M_T}{D^2[w_t(1 - 0.4a_{gv}) + w_a - 0.4w_{int}]} \quad (62)$$

where w_a is the force per unit circumferential length resisting uplift in the annular region and w_{int} the uplift load per unit circumferential length due to product pressure. The values of w_a and w_{int} can be computed by appropriate formulae in API 650.

Tanks with $J < 0.785$ do not uplift, whereas if $J > 1.54$, the tank is unstable and mechanical anchorage is necessary.

An estimate of the membrane stress σ_{rb} in the base plate due to uplift can be obtained by Eq. 63:

$$\sigma_{rb} = 0.568E \left(\frac{pL(w)}{Et} \right)^{2/3} \quad (63)$$

proposed in EN 1998-4 (European Committee for Standardization 2006b) and written herein in

Liquid Storage Tanks: Seismic Analysis,
Fig. 10 Uplifting parameters of an unanchored tank

Liquid Storage Tanks: Seismic Analysis,

Fig. 11 Maximum vertical uplift of the tank w versus overturning moment M of two fixed-roof unanchored cylindrical tanks; finite element results (Vathi and Karamanos 2014)

more convenient terms. In this equation, L is the uplifted length of the tank which is a function of the uplifting size w , so that $L = L(w)$. The corresponding strain can be computed as follows:

$$\varepsilon_{rb} = \frac{\sigma_{rb}}{E} = 0.568 \left(\frac{pL(w)}{Et} \right)^{2/3} \quad (64)$$

When significant uplift takes place in large-diameter tanks, the state of stresses in the uplifted part of the base plate at the ultimate limit state is dominated by plate bending (including the effect of the pressure acting on the tank base), not by membrane stresses. In such cases, a finite element analysis method should be used for the calculation of the state of stresses.

As far as the plastic rotation of the base plate connection is concerned, it is recommended to design the bottom annular ring with a thickness less than the wall thickness, so as to avoid flexural yielding at the base of the wall.

Finally, the plastic rotation associated to uplift w at the edge of the tank and a base separation of L can be computed as follows:

$$\theta_p = \left(\frac{2w}{L} - \frac{w}{2R} \right) \quad (65)$$

which should be less than the rotation capacity of the welded connection.

Forces on Anchors

In the case of mechanically anchored tanks, the seismic design load, P_{AB} , at each anchor

necessary to design the anchor can be calculated by the following simple equation:

$$P_{AB} = N \left(\frac{\pi D}{n_A} \right) \quad (66)$$

where N is the maximum tensile force per unit circumferential length given in Eq. 47 and n_A is the number of anchors around the tank circumference.

Soil-Tank Interaction

For tanks on relatively deformable ground, the base motion can be significantly different from the free-field motion; in general the translational component is modified and there is also a rocking component. Moreover, for the same input motion, as the flexibility of the ground increases, both the fundamental period of the tank-fluid system and the total damping increase, reducing the peak seismic force. The increase in the fundamental period is more pronounced for tall, slender tanks, because the contribution of the rocking component is greater. The reduction of the peak seismic force, however, is less pronounced for tall tanks, since the damping associated with rocking is smaller than that associated with horizontal translation.

The convective periods and pressures are assumed not to be affected by soil-structure interaction. A simple procedure, initially proposed for buildings and consisting of an increase of the fundamental period and of the damping of the structure on a rigid soil, has been extended to the impulsive (rigid and flexible) components of the response of tanks (Habenberger and Schwarz 2002). A good approximation can be obtained through the use of an equivalent simple oscillator with parameters adjusted to match frequency and peak response of the actual system. The properties of this “substitute oscillator” are given in the form of graphs, as functions of the ratio H/R described in the above publications.

An alternative procedure to account for soil flexibility has been suggested by Priestley et al. (1986). The procedure suggests the modification of the frequency and the damping of the impulsive motion, based on the work of

Gazetas (1983), and the corresponding equations for the modified natural periods and damping values can be found in Annex A, Section A.7.2.2 of EN 1998-4 (European Committee for Standardization 2006b).

Seismic Action on Nozzles (Pipe Attachments)

The region of the tank shell where piping is attached to should be designed to resist the forces transmitted by the piping amplified by an appropriate load factor. If reliable information is not available for the attached piping system or an accurate analysis cannot be performed, a relative displacement Δ between the first anchoring point of the piping and the tank should be assumed to take place in the most adverse direction and used for the analysis of the nozzle, with a value, as suggested in EN 1998-4 (European Committee for Standardization 2006b):

$$\Delta = \frac{x}{x_0} d_g \quad (67)$$

In the above expression, x_0 is a reference length equal to 500 m, x the distance between the anchoring point of the piping and the point of connection with the tank, and d_g the design ground displacement.

An alternative methodology for calculating actions on piping attachments is stated by API 650 (American Petroleum Institute 2007). Piping systems shall provide a minimum imposed displacement in the piping, supports, and tank (Table E-8 of API 650) in lieu of a more detailed analysis of the piping system and its connection.

Seismic Resistance of Liquid Storage Tanks

Limit States (General)

The failures against which liquid storage tanks have to be verified when subjected to seismic loading are:

- Development of elephant's foot buckling at the lower course of the tank

- Buckling at the top of the tank due to the alternating sign of the hydrostatic and hydrodynamic pressures
- Rupture or leakage because of the increased induced hoop hydrodynamic stresses
- Plastification of the base plate in unanchored tanks due to uplifting
- Failure of the anchor bolts
- Failure at the nozzles and piping system, especially in the case of unanchored tanks
- Sliding of the tank
- The connection area of hydraulic/piping systems with the tank (nozzles) shall be verified to accommodate stresses and distortions due to relative displacements between tanks or between tanks and soil, without their functions being impaired (see also provisions for attached piping).

The above modes are examined below in more detail. It is noted that a thorough presentation of each failure mode and its modeling in the course of a seismic design and analysis procedure is out of the scope of the present chapter.

Shell Buckling Mode

The maximum actions (e.g., membrane forces and bending moments, circumferential or meridional) induced in the seismic design shall be less or equal to the resistance of the shell evaluated as in the persistent or transient design situations. For the cylindrical steel shell buckling by vertical (meridional) compression with simultaneous action of hoop tension due to hydrostatic loading (“elephant’s foot mode of failure”) is a critical situation.

Steel tanks with very thin shells have also displayed another type of shell buckling mode involving diamond-shaped buckles at a distance above the base of the tank, usually with low internal pressure.

Observations from previous seismic events have indicated that buckling of the lower courses has occasionally resulted in the loss of tank contents due to weld or attached piping fracture and, in some cases, total collapse of the tank. Therefore, in the course of a seismic design procedure, it should be verified that the tank is safe against local buckling. Thus, to ensure “integrity” of the tank under the seismic action against elephant’s foot buckling:

- The geometry (thickness) of the tank should be such that it can withstand significant compressive stresses without buckling in the case of an earthquake.

Section 8.5 and Annex D of EN 1993-1-6 (European Committee for Standardization 2007), paragraphs D.1.2 and D.1.5, give a systematic methodology for the calculation of cylindrical shell resistance against meridional axial compression in the presence of hoop tension due to internal pressure. Moreover, paragraph A.10 of EN 1998-4 (European Committee for Standardization 2006b) provides alternative rules for internally pressurized shell buckling, based on the work by Rotter (1990).

Roof Damage

Sloshing motion of tank liquid contents occurs during earthquake motion. Tank inspections following strong earthquakes indicated that the actual amplitude of liquid surface elevation may be of several meters in some cases. For full or near-full tanks, resistance of the roof to the impact of sloshing waves results in an upward (internal) loading on the roof which may cause buckling of the upper courses of the shell walls. Damage may also occur at the frangible joints between the walls and the ribs of the roof, with accompanying spillage of tank contents over the top of the tank wall.

In practice, a freeboard shall be provided having a height not less than the calculated height of the slosh waves. Freeboard at least equal to the calculated height of slosh waves shall be provided, if the contents are toxic or if spilling could cause damage to piping or scouring of the foundation. Freeboard less than the calculated height of the slosh waves may be sufficient, if the roof is designed for the associated upward pressure or if an overflow spillway is provided to control spilling of contents. Damping devices against sloshing, e.g., grillages or vertical partitions, can be used to reduce sloshing wave height. If the tank has no rigid roof, adequate freeboard is

Liquid Storage Tanks: Seismic Analysis, Fig. 12 Hoop hydrodynamic stresses, σ_h , and meridional stresses, σ_z , on the tank wall

needed to prevent undesirable effects of liquid spilling.

Hoop Stresses (Hydrostatic and Hydrodynamic)

Tensile hoop stresses, σ_h , may increase due to hydrodynamically induced pressures between the fluid and the tank and exceeding allowable hoop stress, leading to fracture and leakage, as shown in Fig. 12. This phenomenon has occurred extensively in old riveted tanks, where leakage at the riveted joints resulted from seismic pressure-induced yielding. Welded steel tanks with butt-welded joints are less vulnerable in such a rupture because of better ductility of the welded joints; however, large tensile hoop stresses, σ_h , can contribute to the premature development of elephant foot buckling near the tank base due to excessive meridional compression, σ_z , and its interaction with the hoop stress σ_h .

Relevant shell design provisions for tensile stress failure exist in all specifications, where allowable stresses and efficiency factors for welds are specified. If overmatched butt-welded joints are used, efficiency factor is usually equal to unity.

Base Plate Connection Failure

In the case of unanchored tanks, uplifting may occur and, instantaneously, the welded connection between the tank bottom plate and the tank shell at the uplifting side of the tank is subjected to significant tensile stresses that may lead to weld failure. This may result in fracture at the base plate welded connection and immediate loss

of tank content. To avoid this failure the plastic rotation at the welded connection, calculated through Eq. 65, should be limited to a certain value. Such limit values are stated in Section A.9 of EN 1998-4 (European Committee for Standardization 2006b). In addition, strong cyclic loading at the weld, associated with plastic rotation less than the allowable plastic rotation of the connection, may result in fracture due to low-cycle fatigue (Prinz and Nussbaumer 2012).

Resistance of Anchor Bolts

Numerous steel tanks, especially tall (slender) tanks, are anchored with bolts or straps. However, these anchors may be insufficient to withstand the total imposed load in strong earthquake events and can be damaged, in the form of anchor pull-out, stretching, or rupture. One should consider that failure of an anchor does not necessarily lead to tank collapse or loss of tank contents. On the other hand, failure of a significant number of bolts may lead to failure of the tank supporting system and eventually to tank overturning and loss of contents.

The resistance of an anchor bolt subjected to tension can be considered as a fraction of the ultimate force, defined as the product of the bolt net area with the ultimate stress of the bolt material. Bolts should also be designed so that their attachment plate to the shell tank does not fail in shear. Finally, the bolts should be adequately anchored and designed against pullout or punching shear failure.

Failure at Attached Piping Locations

Piping systems connected to tanks should be designed in a way that during earthquakes the potential deformation of the connection location with piping is accommodated. If not, fracture may occur at this area, at the vicinity of the weld leading to loss of content (Wieschollek, Hoffmeister, and Feldmann 2013). To minimize the risk of such a failure, piping systems should provide sufficient flexibility to avoid release of the product by failure of the piping system. To achieve this, the piping system and supports shall be designed so as to not induce significant mechanical loading on the tank shell attachment.

Local loads at piping connections shall be considered in the design of the tank shell. Moreover, the piping shall be designed to minimize unfavorable effects of interaction between tanks and other structures. Mechanical devices which add flexibility to the piping connection, such as bellows, expansion joints, and other flexible components, may be used when they are designed for seismic loads and displacements.

If there is no flexibility loop between the point where the pipe is independently (rigidly) supported and the nozzle, and there are relative anchor motions, the tank nozzle and tank shell should be appropriately checked. Construction of a flexibility loop in the pipe between the tank nozzle and the independent piping supports is always beneficial.

Stability Against Sliding

In general, sliding of the tank should be prevented during a seismic event. The resisting shear force at the interface of the base of the structure and the foundation shall be evaluated taking into account the effects of the vertical component of the seismic action.

For the evaluation of the sliding resistance, the transfer of the total lateral shear force between the tank and the subgrade shall be considered. For self-anchored (unanchored) flat-bottom steel tanks, the overall horizontal seismic shear force shall be resisted by the friction between the tank bottom and the foundation or subgrade. Self-anchored storage tanks shall be proportioned such that the seismic base shear, Q , does not exceed a limit value Q_s , defined as follows:

$$Q_s = \mu(W_s + W_r + W_f + W)(1 - 0.4a_{gv}) \quad (68)$$

where μ is an appropriate friction coefficient.

Limited sliding in unanchored tanks may be acceptable, only if the implications of sliding for the connections between the various parts of the structure and between the structure and any piping are taken into account in the tank analysis and the corresponding verifications.

Summary

In this chapter, important information concerning the seismic analysis of circular cylindrical liquid storage tanks is stated. This information includes a short presentation of the current design standards, a short reference to the seismic input in the course of spectral analysis, the seismic actions that occur during a seismic event, and the resistance of the tank to these actions. Both rigid and flexible tanks that are anchored or unanchored may be considered. It is important to remember that liquid-tank interaction is a key issue for tank seismic response. Furthermore, the total motion can be decomposed in an impulsive part that follows the motion of the container and a convective part, associated with free surface liquid sloshing.

Using the analysis described in the present chapter, for determining the seismic action and considering all possible failure modes, the seismic response of a liquid storage tank can be evaluated rationally and effectively towards safeguarding its structural integrity.

Global centroid-moment-tensor inversion; Long-period earthquake analysis

Introduction

Long-period moment-tensor inversion is a methodology to estimate first-order earthquake parameters by inverse modeling of long-period seismograms, typically recorded at teleseismic distances. Data from large numbers of globally distributed digital broadband seismographs and knowledge of elastic wave propagation through the heterogeneous Earth currently make possible the uniform determination of moment tensors of earthquakes with $M \geq 5.0$. The Global CMT Project is an ongoing systematic research effort to study all significant earthquakes occurring worldwide using long-period moment-tensor inversion and to maintain and curate a catalog of the resulting earthquake parameters.

Earthquakes are complex geophysical events with the potential to cause vast destruction. When and where earthquakes occur and a characterization of their size and effects form knowledge of scientific and societal value. For example, systematic analysis of earthquakes led to the mapping of seismic belts and, subsequently, the understanding that most earthquakes occur at the boundaries of tectonic plates. The monitoring and cataloging of earthquake characteristics and their geographical distribution were key ingredients for the development and acceptance of the theory of plate tectonics.

The size of an earthquake is a fundamental descriptive parameter. It was traditionally assessed using the maximum intensity of ground shaking experienced near the earthquake or, following the development and global deployment of seismographs, by measurement of the logarithmic amplitude of weak ground motion recorded at large distances, corrected for distance and attenuation effects – the quantity known as the earthquake magnitude. Since most earthquakes are not felt and the determination of a magnitude is an analysis step that often accompanies earthquake detection and location, the seismic magnitude is the most commonly reported measure of earthquake size. While useful in determining the relative sizes of earthquakes and for estimating and predicting the frequency of earthquakes of a given magnitude using observed frequency–magnitude relationships, traditional magnitude scales are phenomenological, empirical, and imprecise and cannot be directly related to physical properties of the earthquake.

The fundamental insight that earthquakes reflect the sudden relaxation of tectonic stresses across faults dates back more than a century. A deeper physical and quantitative understanding of the relationship between fault motion and seismic-wave generation developed in the 1960s and 1970s. In particular, the seismic moment M_0 was identified as the central physical parameter that describes the size of an earthquake. An earthquake that involves average relative motion $\bar{d}$ of the two sides of a fault over an area A has a seismic moment $M_0 = \mu A \bar{d}$, where μ is the rigidity of the rock surrounding the fault. The seismic moment carries units of force $\times$ distance and represents the strength of two perpendicular force couples with no net rotation acting at the hypocenter. The double-couple model of forces is consistent with the notion that the elastic rebound in an earthquake is the response to sudden unrestrained stress at the earthquake fault. This “stress glut” is a tensor quantity closely related to the moment tensor of the earthquake. It reflects the strength and three-dimensional geometry of fault motion. From the seismic moment given in Nm, a

moment magnitude M_W (sometimes simply M) can be calculated using a standard formula,

$$M_W = \frac{2}{3}(\log_{10} M_0 - 9.1), \quad (1)$$

designed to agree, on average, with traditional earthquake magnitudes for moderate earthquakes (Kanamori 1977). The seismic moment and the moment magnitude are the preferred modern measures of earthquake size. The moment-tensor elements are directly related to the strike and dip angles of the earthquake fault and the rake angle of fault motion in the earthquake.

The development of detailed models of the layered elastic and density structure of the Earth in the 1970s and 1980s made possible the accurate forward calculation of the seismic wavefield caused by forces acting in the Earth. In particular, in the formalism of the Earth's long-period elastic normal modes, the excitation of seismic waves by body forces and moment-tensor sources is straightforward (Gilbert 1971). Linear elastic wave theory thus provides the framework in which earthquake source characteristics can be deduced from observed seismic waves. At long periods, the seismic wavefield is simple and can be explained by a small number of fundamental earthquake parameters.

Improvements in the digital recording of broadband ground motion on a global scale during the 1980s provided the observations needed for systematic application of inverse modeling methods to characterize global earthquake activity. At present, several groups routinely determine moment tensors and seismic moments for earthquakes worldwide. Knowledge about global seismic activity collected and derived from these efforts is important for improved understanding of earthquake sources, active tectonics, and global seismic hazard.

Long-Period Earthquake Analysis

Earthquake fault rupture is complex. The slip on the fault is distributed heterogeneously over a

surface, and the seismic rupture and slip take time to complete. Seismic waves excited by the earthquake reflect the full complexity of the earthquake forces, but the observed vibrations average out the details in a way that depends on period and wavelength. At long periods and long wavelengths, the effect of the entire earthquake is well represented by a small number of point-source parameters. Analogously to distributions of other physical quantities, such as masses or forces, it is useful to expand the description of the earthquake source using spatial and temporal moments. Only the lowest moments of the source influence the long-period source radiation. At the same time, the lowest moments carry fundamental information about the earthquake source including the seismic moment and the fault geometry.

The Moment Tensor and Its Centroid

The spatial and temporal complexity of an earthquake can be described by a distribution of stress glut in space and time, $\dot{\Gamma}_{ij}(\mathbf{r}, t)$. The zeroth-order moment tensor is the time and space integral of $\dot{\Gamma}_{ij}(\mathbf{r}, t)$,

$$M_{ij} = M_{ij}^{(0,0)} = \int_{t_1}^{t_2} \int_V \dot{\Gamma}_{ij}(\mathbf{r}, t) dV dt, \quad (2)$$

where the zeros (0,0) in the superscript refer to the zeroth spatial and temporal moments, respectively. In spherical coordinates, the elements of the moment tensor are

$$\mathbf{M} = \begin{bmatrix} M_{rr} & M_{r\theta} & M_{r\varphi} \\ M_{\theta r} & M_{\theta\theta} & M_{\theta\varphi} \\ M_{\varphi r} & M_{\varphi\theta} & M_{\varphi\varphi} \end{bmatrix}, \quad (3)$$

with (r, θ, φ) denoting (up, south, east). Just as the stress-glut-rate tensor, the moment tensor is symmetric:

$$M_{r\theta} = M_{\theta r}, M_{r\varphi} = M_{\varphi r}, M_{\theta\varphi} = M_{\varphi\theta}.$$

For a planar fault with a strike angle ϕ and dip angle δ and with earthquake fault motion

described by the rake angle λ , the moment-tensor elements are

$$\begin{aligned} M_{rr} &= M_0 \sin 2\delta \sin \lambda \\ M_{\theta\theta} &= -M_0(\sin \delta \cos \lambda \sin 2\phi + \sin 2\delta \sin \lambda \sin^2 \phi) \\ M_{\varphi\varphi} &= M_0(\sin \delta \cos \lambda \sin 2\phi - \sin 2\delta \sin \lambda \cos^2 \phi) \\ M_{r\theta} &= -M_0(\cos \delta \cos \lambda \cos \phi + \cos 2\delta \sin \lambda \sin \phi) \\ M_{r\varphi} &= M_0(\cos \delta \cos \lambda \sin \phi - \cos 2\delta \sin \lambda \cos \phi) \\ M_{\theta\varphi} &= -M_0\left(\sin \delta \cos \lambda \cos 2\phi + \frac{1}{2} \sin 2\delta \sin \lambda \sin 2\phi\right), \end{aligned} \quad (4)$$

where M_0 denotes the seismic moment of the earthquake.

A point-source representation of a seismic source can be expressed as

$$\dot{\Gamma}_{ij}(\mathbf{r}, t) = M_{ij} \delta^3(\mathbf{r} - \mathbf{r}_s) \delta(t - t_s), \quad (5)$$

where $(\mathbf{r}_s, t_s)$ is the location and time of the instantaneous earthquake. The location of the point source that is most representative of a given stress-glut distribution can be defined by considering the first moments of the stress-glut-rate distribution. The first spatial moment of $\dot{\Gamma}_{ij}(\mathbf{r}, t)$ around some reference location $\mathbf{r}_h$ is defined as

$$M_{ijp}^{(1,0)} = \int_{t_1}^{t_2} \int_V \dot{\Gamma}_{ij}(\mathbf{r}, t) (r_p - r_{hp}) dV dt, \quad (6)$$

where the subscript p represents one of the three spatial coordinates (r, θ, φ) . The first temporal moment around some reference time t_h is

$$M_{ij}^{(0,1)} = \int_{t_1}^{t_2} \int_V \dot{\Gamma}_{ij}(\mathbf{r}, t) (t - t_h) dV dt. \quad (7)$$

The time and location for which the sum of the squares of these four moments is minimum can be considered the center of the stress-glut-rate distribution and defines the moment-tensor centroid. A point-source representation of an earthquake is therefore given by the following ten parameters: the six independent elements of M_{ij} , the centroid location $\mathbf{r}_c$ (latitude, longitude, depth), and the centroid time t_c .

A common extension to the point-source representation in Eq. 5 is to incorporate a duration of faulting or, more generally, source activity. In a moment expansion of the stress glut, this corresponds to a nonzero second temporal moment of the stress glut, $M_{ij}^{(0,2)}$. A convenient way to incorporate this complexity is to introduce a source-time function $S(t)$ and write the source representation as

$$\dot{\Gamma}_{ij}(\mathbf{r}, t) = M_{ij} \delta^3(\mathbf{r} - \mathbf{r}_s) \delta(t - t_s) * S(t; \tau_h), \quad (8)$$

where $*$ indicates convolution and $S(t; \tau_h)$ is a function of unit area, symmetric around $t = 0$, with a total duration $2\tau_h$.

Synthetic Seismograms and Inversion

The relationship between an instantaneous moment-tensor point source and the ground motion $u(\mathbf{r}, t)$ at an arbitrary point on the Earth is illustrated by the expression describing the excitation and summation of the Earth's normal modes,

$$u(\mathbf{r}, t) = \sum_k \left[1 - \cos \omega_k(t - t_s) e^{-\alpha_k(t - t_s)} \right] \mathbf{M} : \mathbf{e}_k(\mathbf{r}_s) \mathbf{s}_k(\mathbf{r}), \quad (9)$$

where the summation is over modes k , ω_k and α_k are the normal-mode frequency and decay constants, $\mathbf{e}_k(\mathbf{r}_s)$ is the strain of the k th mode at the source location, and $\mathbf{s}_k(\mathbf{r})$ is the displacement of the k th mode at the receiver location. From this expression, it is clear that there is a linear relationship between the moment-tensor elements and the resulting ground motion. The linear relationship is not limited to the normal-mode formulation but is a consequence of linear elastic theory.

For convenience, the six independent elements of the moment tensor can be written as a vector f_i , with $f_1 = M_{rr}$, $f_2 = M_{\theta\theta}$, $f_3 = M_{\varphi\varphi}$, $f_4 = M_{r\theta}$, $f_5 = M_{r\varphi}$, and $f_6 = M_{\theta\varphi}$. Ground motion u_k at a location $\mathbf{r}$ in a direction given by the subscript k and caused by a moment-tensor

Long-Period Moment-Tensor Inversion: The Global CMT Project,

Fig. 1 Kernel east–west seismograms for a hypothetical deep earthquake ($h = 500$ km) in Bolivia recorded at a station in Los Angeles, California. Each trace corresponds to the motion associated with a single moment-tensor element f_i . The ground motion has been filtered between 30 and 300 s

point source at $\mathbf{r}_s$ with a time history $S(t; \tau_h)$ can then generally be written as

$$u_k(\mathbf{r}, t) = \sum_{i=1}^6 \psi_{ik}(\mathbf{r}, \mathbf{r}_s, t) * S(t; \tau_h) \cdot f_i, \quad (10)$$

where the kernel seismograms $\psi_{ik}(\mathbf{r}, \mathbf{r}_s, t)$ represent the individual contributions to the seismogram from each moment-tensor component i . Figure 1 shows the six moment-tensor kernels for a hypothetical deep earthquake in Bolivia recorded on the east–west component of a seismometer in Los Angeles, California. The different shapes of the kernels illustrate the linear independence of the different moment-tensor contributions to any recorded ground motion.

Equation 10 and Fig. 1 suggest the least-squares minimization problem

$$\min \left(\int_{t_1}^{t_2} [o_k(t) - u_k(t)]^2 dt \right) \quad (11)$$

to estimate the six moment-tensor elements f_i , where $o_k(t)$ represents the observed seismogram, t_1 and t_2 define a signal time window, and it is understood that the observed and synthetic waveforms have been filtered in the same way. Expressed as in Eqs. 10 and 11, the inverse

problem for f_i is strictly linear and can be solved in a single step. However, this formulation is based on a fixed source location ($\mathbf{r}_s, t_s$). In practice, this location is a reported hypocenter that may not correspond closely to the optimal moment-tensor point-source location and time, the centroid ($\mathbf{r}_c, t_c$). To estimate the centroid as well as the moment-tensor elements, additional steps are needed.

When an initial estimate of the moment-tensor elements has been obtained by solving the inverse problem in Eq. 11, the change in the synthetic seismograms with respect to small changes in source location and the moment-tensor elements can be written as

$$\begin{aligned} \delta u_k(t) = u_k(t) - u_k^{(0)}(t) = & b_k(t) \delta r_s \\ & + c_k(t) \delta \theta_s + d_k(t) \delta \varphi_s + e_k(t) \delta t_s \\ & + \sum_{i=1}^6 \psi_{ik}^{(0)}(t) * S(t) \cdot \delta f_i, \end{aligned} \quad (12)$$

where the superscript (0) refers to the synthetic seismogram and moment-tensor kernels calculated for the initial source location. The quantities b_k , c_k , d_k , and e_k represent linear-perturbation kernels,

$$\begin{aligned}
b_k(t) &= \sum_{i=1}^6 \frac{\partial \psi_{ki}^{(0)}}{\partial r_s}(t) * S(t) \cdot f_i^{(0)} \\
c_k(t) &= \sum_{i=1}^6 \frac{\partial \varphi_{ki}^{(0)}}{\partial \theta_s}(t) * S(t) \cdot f_i^{(0)} \\
d_k(t) &= \sum_{i=1}^6 \frac{\partial \varphi_{ki}^{(0)}}{\partial \varphi_s}(t) * S(t) \cdot f_i^{(0)} \\
e_k(t) &= \sum_{i=1}^6 \frac{\partial \varphi_{ki}^{(0)}}{\partial t_s}(t) * S(t) \cdot f_i^{(0)},
\end{aligned} \tag{13}$$

reflecting changes in the seismogram due to a small perturbation in the source location. A second step in the inversion can then be formalized by minimizing the remaining misfit between observed and synthetic waveforms with respect to perturbations in the moment-tensor elements as well as the centroid parameters,

$$\min \left(\int_{t_1}^{t_2} \left[\left(o_k(t) - u_k^{(0)}(t) \right) - \delta u_k(t) \right]^2 dt \right). \tag{14}$$

By iteratively updating the moment-tensor and centroid estimates, as well as the corresponding synthetic seismograms and kernels, and inverting the residual signal for additional perturbations in the source parameters, an optimal estimate of the point-source parameters is obtained.

The preceding paragraphs summarize the theoretical developments and technical approaches described by Gilbert (1971) and Dziewonski et al. (1981). Dziewonski et al. (1981) introduced the full formalism for the simultaneous estimation of the moment tensor and the source centroid, giving rise to the concept of the centroid-moment tensor, or the CMT. The CMT concept is general and can in principle be used with any recorded seismograms, provided that the point-source approximation remains valid. Conditions for success are that high-quality, well-calibrated seismograms are available and that synthetic waveforms corresponding to the observed seismograms can be generated with sufficient fidelity to allow a quantitative comparison.

The Global CMT Project

A systematic effort to use long-period centroid-moment-tensor inversion for the study of global seismicity was initiated by A. M. Dziewoński and J. H. Woodhouse at Harvard University in the early 1980s. This sustained analysis effort was known as “the Harvard CMT Project” and the catalog of earthquake parameters that resulted as “the Harvard CMT Catalog.” In 2006, the research effort moved with G. Ekström and M. Nettles to Lamont–Doherty Earth Observatory of Columbia University, where it continues under the name “the Global CMT Project,” with the primary research goal of curating, improving, and extending the CMT catalog of global earthquake focal mechanisms (Ekström et al. 2012).

Proof of Concept

In the first demonstration of the CMT approach (Dziewonski et al. 1981), it was shown that CMTs could be calculated for globally distributed earthquakes as small as $M_w = 5.5$ by least-squares inversion of long-period ($T > 45$ s) body-wave seismograms recorded on a sparse network of stations. The synthetic seismograms were calculated by summation of normal modes for the spherically symmetric Preliminary Reference Earth Model (PREM) (Dziewonski and Anderson 1981). Three specific circumstances explain the success of this approach. First, the general characteristics of the seismic source are such that a point-source approximation is appropriate at the periods considered. For example, a typical duration of an $M = 6.0$ earthquake is 5 s, and a typical fault dimension is 10 km, both of which are small compared with a wave period of ~ 50 s and a wavelength of ~ 200 km. Second, the background seismic noise in the Earth is low at periods of 30–200 s. Even relatively small earthquakes generate ground motion in this period range that is observable at large distances with modern digital instrumentation. Third, while the three-dimensional (3D) elastic heterogeneity of the Earth is significant, the selected part of the long-period seismic wavefield can be simulated with high accuracy using a one-dimensional (1D) Earth model. In particular, seismic body-wave

phases diving deep into the Earth's mantle and core typically do not exhibit travel-time residuals greater than several seconds, which is small with respect to the periods used in the CMT waveform inversion.

Project Evolution

Early applications of the CMT approach were constrained by the very limited availability of high-quality digital seismograms. Only 10–20 stations provided digital data on a global scale in the early 1980s. In addition, although the importance of the Earth's shallow elastic heterogeneity was appreciated, the 3D elastic structure of the Earth was unknown. Methods for synthesizing seismograms in heterogeneous 3D Earth structure were also limited and not appropriate for routine calculations on then-available computers. Rapid progress occurred during the 1980s and 1990s. New networks of globally distributed seismographic stations were deployed, soon providing broadband data in near-real time that could be incorporated in CMT analysis. Low-degree tomographic models of the Earth's upper mantle were developed, and new approximate methods for synthesizing normal-mode seismograms for these models in a computationally efficient manner made possible the inclusion of very long-period ($T > 135$ s) surface waves in the CMT analysis. These waves, often called mantle waves because their primary sensitivity is to elastic structure in the mantle, are particularly useful for the analysis of large earthquakes since their long period and wavelength make the point-source approximation valid even for very large events.

Since 1984, the methodology used in the CMT project for synthesizing normal-mode seismograms in an elliptical and heterogeneous 3D Earth has been based on the path-average approximation. In this approach, the average 1D structure for the minor arc and the great circle connecting the earthquake and each recording station are calculated from an existing 3D Earth model. Small adjustments in the normal-mode frequencies corresponding to deviations from the global-average 1D Earth structure are calculated for each path and applied in the mode sum.

To account for the different average structures along the great-circle and minor-arc paths, a fictitious shift in the geographical location of the earthquake is also applied for each mode, using an approach introduced by Woodhouse and Dziewonski (1984). This method for seismogram synthesis corrects the phase of long-period seismic waves for the effect of large-wavelength 3D heterogeneity to first order and retains the computational efficiency of normal-mode summation.

New generations of tomographic models of the Earth's mantle have led to an improved ability to match long-period body waves and very long-period surface waves (mantle waves). These 3D models have not, however, been adequate for matching the large propagation delays observed for fundamental-mode Love and Rayleigh surface waves at periods shorter than 100 s. In addition, the linear-perturbation approach to correcting the mode sum is inappropriate for heterogeneity that causes travel-time delays of the same order as, or longer than, the period of the wave. The value of including intermediate-period surface waves in the CMT analysis is that these waves frequently are the largest phases in long-period seismograms. Following the development in the late 1990s of high-resolution global dispersion models for Love and Rayleigh waves, the possibility arose to incorporate propagation delays from such maps in the calculation of the fundamental-mode contribution to the synthetic seismograms. In 2004, a hybrid approach to the calculation of synthetic seismograms was introduced in the CMT analysis. The body-wave portion and very long-period mantle-wave portion of the wavefield are synthesized using the path-average normal-mode approach, while intermediate-period minor-arc fundamental-mode surface waves are calculated using a surface-wave approach, with phase delays derived from surface-wave phase-velocity maps (Ekström et al. 1997). The consideration of intermediate-period surface waves allows for the analysis of smaller earthquakes than was previously possible and offers improved constraints on the moment tensors for shallow earthquakes.

Current Practice

Analysis of seismicity in the Global CMT Project is divided into calendar months. The analysis is initiated 2–3 months after real time and is completed before the end of 4 months. Earthquakes that have the potential to yield robust CMT results are selected for analysis, primarily from the hypocenter catalog of the National Earthquake Information Center (NEIC) of the United States Geological Survey (USGS). The current objective is to attempt analysis for all earthquakes $M_W \geq 5.0$. Because of the large uncertainties in traditional magnitudes, all events with m_b or $M_S \geq 4.8$ are selected for analysis. This typically leads to a monthly list of ~300 candidate earthquakes, of which more than half are successfully analyzed.

Seismograms are collected from the IRIS-USGS Global Seismographic Network (seismic network codes II and IU) with additional data from stations of the China Digital Seismograph Network (IC), the Geoscope (G), Mednet (MN), Geofon (GE), and Caribbean (CU) networks. Normally, more than 150 stations are available for any earthquake. Figure 2 shows a map with the stations contributing to CMT analysis for earthquakes in 2012.

Three-component data from all stations are extracted for each event, and the responses are equalized by deconvolution of the instrument response and convolution with standard band-pass filters that depend on the data type. Rotated horizontal components (longitudinal and transverse) are constructed and considered in the analysis. Three types of data are used: (1) body waves, which are the signals that arrive in the time window before the arrival of the minor-arc surface waves; (2) mantle waves, which consist of up to 4.5 h of data, including several very long-period Love and Rayleigh wave arrivals (e.g., G1–G4 and R1–R4); and (3) intermediate-period surface waves, which consist of a time window centered on the minor-arc arrival times for surface waves.

Filtering strategies and data selection depend on the earthquake magnitude. Body-wave data for earthquakes $5.5 \leq M_W \leq 6.5$ are filtered to displacement between 150 and 40 s. For earthquakes $M_W < 5.5$, the seismograms are filtered to velocity. For earthquakes $M_W \geq 6.5$, the waves are filtered to displacement between 150 and 50 s. Mantle-wave data are considered only for earthquakes $M_W \geq 5.5$, since smaller earthquakes do not produce observable signals in this band.

Long-Period Moment-Tensor Inversion: The Global CMT Project, Fig. 2 Map showing the locations of 206 stations that contributed seismograms to the GCMT

analyses in 2012. Stations that contributed data for more than 200 earthquakes are shown with *hexagons*; other stations are shown with *squares*

For earthquakes $M_W \leq 7.0$, the waves are filtered to displacement between 350 and 125 s. For earthquakes $M_W > 7.0$, the filter is shifted in period with earthquake size so that for earthquakes $M_W > 8.0$, the range is 450–200 s. Intermediate-period surface waves for earthquakes $M_W \geq 5.5$ are filtered to displacement between 150 and 50 s. For smaller earthquakes, the response is modified to velocity, to emphasize the shorter-period signals, which are less obscured by noise. Intermediate-period surface waves are not considered for earthquakes deeper than 300 km.

The three data types provide complementary constraints on the seismic source. Body waves sample the focal sphere of the earthquake in a relatively uniform fashion. Intermediate-period surface waves provide good constraints for smaller earthquakes. The very long-period mantle waves are less sensitive to the spatial extent and temporal history of the seismic source, an advantage for large earthquakes. Seismograms of the three wave types are weighted in the CMT inversion in such a way that the mantle waves do not contribute for earthquakes $M_W < 5.5$, have a relative weight that increases linearly with magnitude for $5.5 \leq M_W \leq 6.5$, and are weighted fully for earthquakes $M_W > 6.5$. Body and surface waves are weighted fully for $M_W < 6.5$, have a decreasing relative weight for $6.5 \leq M_W \leq 7.5$, and do not contribute for earthquakes with $M_W > 7.5$ since, for earthquakes of this size, the signal at shorter periods is dominated by spatial and temporal source complexities that are not accounted for in the CMT inversion.

Data selection is necessary to eliminate erroneous seismograms and to exclude traces that are dominated by noise or signals not associated with the earthquake. An automated editing program is used to assist with the data-selection tasks, including assessing observed signal levels and waveform fits in predicted time windows across the network and eliminating faulty and outlying traces. The final inversion results and corresponding fit to the data undergo human review. The validity and quality of the result is assessed based on the total number of seismograms that were fit in the inversion and

the reduction in data variance obtained. The convergence and stability of the results are used as additional criteria. For small earthquakes and occurrences of overlapping signals from two or more earthquakes, careful human editing of the waveforms is required for the generation of stable and reliable results.

An example of the quality of fit achieved between observed and model waveforms is shown in Fig. 3, with surface-wave seismograms observed at a number of stations at different distances and azimuths from the $M_W = 6.1$ Emilia-Romagna, Italy, earthquake of May 20, 2012.

While in theory all six elements of the moment tensor are resolvable from the data, in practice, trade-offs among the diagonal elements of the moment tensor make the isotropic component of the moment tensor, $M_{rr} + M_{\theta\theta} + M_{\varphi\varphi}$, poorly constrained, except for large and deep earthquakes. However, because the stress glut associated with tectonic faulting is not expected to have a significant isotropic component, there is no expectation that the isotropic component for standard earthquakes should be nonzero. In the CMT inversions, the trace of the moment tensor is therefore constrained to equal zero, $M_{rr} + M_{\theta\theta} + M_{\varphi\varphi} = 0$. In addition, for some earthquakes, the focal depth of the source centroid is held fixed in the inversion. A minimum source depth of 12 km is used to reduce instabilities that can occur in long-period moment-tensor inversions for sources located at or near the Earth's surface. When the depth exhibits persistent instability in the inversions, the depth is fixed at the reported hypocentral depth or at a depth deemed appropriate for the source region.

The source half duration is a parameter assumed in the inversion based on the scalar moment of the event, with an initial estimate derived from the reported magnitude. The empirical relationship $\tau_h = 2.26 \times 10^{-6} M_0^{1/3}$ is used to estimate source half duration, where τ_h is the half duration measured in seconds and M_0 is the scalar moment measured in Nm. Before 2004, the moment-rate function used in the CMT inversions was modeled as a boxcar. Since 2004, the moment-rate function has been modeled as an isosceles triangle with half duration τ_h .

Long-Period Moment-Tensor Inversion: The Global CMT Project, Fig. 3 A selection of observed (*black*) and modeled (*red*) waveforms for the May 20, 2012, $M_W = 6.1$ Emilia-Romagna, Italy, earthquake (875 waveforms were used in the CMT inversion). The station, network, and channel of motion are given to the right of each pair of

waveforms, along with the distance Δ and azimuth ϕ from the earthquake epicenter. In the channel designation, LHZ refers to the vertical component, LHN, LHE, and LH1 refer to recorded horizontal components, and TRANS and LONG refer to components rotated into the directions of transverse and longitudinal motion at the station

The Global CMT Catalog

The catalog of earthquake parameters that has resulted from the research effort described in the preceding paragraphs now contains more than 40,000 earthquakes for the period 1976–2013. It is the most comprehensive and internally consistent global collection of moment tensors. Typical (one-sigma) uncertainties in the estimates of seismic moment are probably no larger than 20 %, implying uncertainties in M_W of approximately 0.05 magnitude units. The catalog is uniform in its methodology, and for large earthquakes, it can be considered uniform and complete, with exception for a small number of large earthquakes that have occurred in the coda of even larger mainshocks. The cumulative moment of earthquakes occurring globally since

1976 is shown in Fig. 4. The figure illustrates the well-known observation that most of the moment is associated with large earthquakes. The largest steps in the graph correspond to the 2004 $M_W = 9.3$ Sumatra earthquake, the 2010 $M_W = 8.8$ Chile earthquake, and the 2011 $M_W = 9.1$ Tohoku earthquake.

Figure 5 shows focal mechanisms from the Global CMT catalog for Eastern Africa, illustrating the use of the catalog for characterizing seismicity and the mode of seismic deformation in areas with limited regional earthquake-monitoring capabilities. The dominant normal-faulting focal mechanisms reflect the process of continental rifting and extension in the area.

For moderate and small earthquakes, general improvements in station coverage and the 2004

Long-Period Moment-Tensor Inversion: The Global CMT Project, Fig. 5 Map showing the Horn of Africa and surrounding area, with focal mechanisms for earthquakes from the GCMT catalog for the period 1976–2013. Background map shows topography. The quadrants

associated with compressional P -wave motion in the lower-hemisphere focal-mechanism plots are shaded red. The radii of the focal mechanisms increase linearly with M_W . The magnitudes of the earthquakes shown range from 4.7 to 7.1

incorporation of intermediate-period surface waves in the CMT analysis have extended the completeness of the catalog to smaller magnitudes. Figure 6 shows a magnitude–frequency diagram for the catalog divided in two parts:

1976–2003 and 2004–2013. The data for 2004–2013 indicate linearity of the slope of the magnitude–frequency relation (and thus completeness) to $M_W = 5.0$, while the earlier data show completeness to about $M_W = 5.4$.

Long-Period Moment-Tensor Inversion: The Global CMT Project, Fig. 6 Magnitude–frequency diagram for earthquakes in the GCMT catalog for two time periods:

(black line) 1976–2003, (red line) 2004–2013. The number of earthquakes is counted in bins of 0.1-magnitude-unit width

The Global CMT catalog is updated routinely and is available from a number of sources. The primary distribution point is the Global CMT website www.globalcmt.org. The full catalog is also available via the website of the Incorporated Research Institutions for Seismology (IRIS), as well as from the International Seismological Centre (ISC) and the NEIC.

Summary

Long-period moment-tensor inversion is a robust method to characterize the geometry and size of earthquakes worldwide. The linear relationship between the amplitude of long-period seismograms and the seismic moment leads to precise and accurate measurements of earthquake size. Catalogs of moment tensors provide primary data on active faults and the geometry of regional seismotectonic deformation.

Global moment-tensor determination is a mature field. Further advances are, however, anticipated as improved 3D models of the Earth's elastic structure are developed and as methods for

calculating synthetic seismograms in a heterogeneous Earth in a routine manner become available.

Introduction

Optically stimulated luminescence (OSL) dating or optical dating provides a measure of time since sediment grains were deposited and shielded from further light or heat exposure, which often effectively resets the luminescence signal (Fig. 1). This technique, as thermoluminescence, was originally developed in the 1950s and 1960s to date fired archeological materials, like ceramics (Aitken 1985). Ensuing research in the 1970s documented that marine and other sediments with a prior sunlight exposure of hours to days were suitable for thermoluminescence dating (Wintle and Huntley 1980). Discoveries in the 1980s and 1990s that exposure of quartz and

feldspar grains to a tunable light source, initially with lasers and later by light-emitting diodes, yields luminescence components that are solar reset within seconds to minutes expanded greatly the utility of the method (Huntley et al. 1985; Hutt et al. 1988; Aitken 1998). In the past 15 years, there have been significant advances in luminescence dating with the advent of single aliquot and grain analysis, and associated protocols with blue/green diodes that can effectively compensate for laboratory-induced sensitivity changes (Murray and Wintle 2003; Wintle and Murray 2006; Duller 2012) and render accurate ages for the past ca. 100,000 years. Most recently, the development of protocols for inducing the thermal transfer of deeply trapped electrons has extended potentially OSL dating to the 10^6 year timescale for well solar-reset quartz and potassium feldspar grains from eolian and littoral environments (Duller and Wintle 2012).

Common silicate minerals like quartz and potassium feldspar contain lattice-charge defects formed during crystallization and from subsequent exposure to ionizing radiation. These charge defects are potential sites of electron storage with a variety of trap-depth energies. A subpopulation of stored electrons with trap depths of ~ 1.3 – 3 meV is a subsequent source for time-diagnostic luminescence emissions. Free electrons are generated within the mineral matrix by exposure to ionizing radiation from the radioactive decay of daughter isotopes in the ^{235}U , ^{238}U , and ^{232}Th decay series and a radioactive isotope of potassium, ^{40}K , with lesser contributions from the decay of ^{85}Rb and cosmic sources. The radioactive decay of ^{40}K releases beta and gamma radiation, whereas the decay in the U and Th series generates mostly alpha particles and some beta and gamma radiation. Alpha particles are about 90–95 % less effective in inducing luminescence compared to beta and gamma radiation. Thus, the population of stored electrons in lattice-charge defects increases with prolonged exposure to ionizing radiation, and the resolved luminescence emission increases with time. Exposure of mineral grains to light or heat (at least 300°C) reduces the luminescence to a low and definable residual level. Often this

Luminescence Dating in Paleoseismology,

Fig. 1 Processes associated with OSL dating. (a) Luminescence is acquired in mineral grains with exposure to ionizing radiation and trapping of electrons. (b) The luminescence for grains is zeroed by exposure to sunlight with erosion and transport. (c) With burial and exposure to ionizing radiation, free electrons are stored in charge defects within grains crystal lattice. (d) Further light

exposure of grains with erosion and transport zeros the luminescence. (e) The grains are buried again and luminescence is acquired with exposure to ionizing radiation. (f) Careful sampling without light exposure and measuring of the natural luminescence, followed by a normalizing test dose (L_n/T_n) compared to the regenerative dose to yield an equivalent dose (D_e) (From Mellett 2013)

luminescence “cycle” occurs repeatedly in many depositional environments with signal acquisition of mineral grains by exposure to ionizing radiation during the burial period and signal resetting (“zeroing”) with light exposure concurrent to sediment erosion and transportation. Often mineral grains that are fresh from bedrock sources have significantly lower luminescence emissions per radiation dose in comparison to grains that have cycled repeatedly. OSL dating provides an estimate of the time elapsed since latest period of burial and, thus, yields a depositional age (Fig. 1).

Principles of Luminescence Dating

The exposure of quartz and feldspar grains to sunlight for >60 s effectively diminishes the time-stored OSL signal to a low definable level. This residual level is the point from which the geological OSL signal accumulates post burial

(Fig. 2). Many types of sediment receive prolonged (>1 h) light exposure with transport and deposition, particularly in eolian, littoral, and sublittoral sedimentary environments. In addition, the inherent residual level is influenced by the susceptibility of the luminescence signal of a specific mineral to solar resetting. The OSL signal of potassium feldspar is usually more resistant to solar resetting than most quartz. There is significant variability in the luminescence properties of quartz and potassium feldspar grains related to crystalline structure, minor and rare-earth impurities, solid-solution relations, number of luminescence cycles (Fig. 1), and radiation history (Mejdahl 1986). Thus, because of this inherent variability in dose sensitivity of quartz and feldspar, analytical procedures for dating often need to be tailored for a specific geologic provenance. The advent of single aliquot regenerative (SAR) dose procedures for quartz (Murray and Wintle 2003; Wintle and Murray 2006) has provided the needed analytical flexibility to compensate for

Luminescence Dating in Paleoseismology,

Fig. 2 (a) Determination of equivalent dose (in grays) using the single aliquot regenerative (SAR) protocols, where the natural luminescence emission is L_n/T_n and the regenerative dose is L_x/T_x ; sensitivity changes are corrected by the administration of a small test dose (e.g., 5 grays). (b) Generalized SAR protocol (From Mellett 2013)

variable luminescence properties of quartz and feldspar grains and laboratory-induced sensitivity changes, particularly associated with preheat treatments and with laboratory beta irradiation (Fig. 2).

OSL dating is predicated on measurements of a specific mineral and particle size, usually quartz or potassium feldspar. Mineral separations are performed by standard techniques using heavy liquids and hydrofluoric acid (HF) to digest non-quartz minerals and etch the outer 10–20 μm of quartz grains, which are affected by alpha radiation. The purity of the quartz extract is primal for effective dating because a small amount contamination (1 %) by potassium

feldspar and other minerals can dominate the luminescence emissions. Multiple soaks in HF may be needed to obtain a pure quartz separate. Purity of the separate is accessed through microscopic inspection and point counting of grain mineralogy. Spectral purity of quartz is often determined by excitation by infrared light from a diode array with subsequent light emissions associated presumably with feldspar contaminants. However, some quartz grains yield considerable emissions with infrared excitation and may host feldspathic or other mineral inclusions; such grains should be analyzed as feldspar grains.

Sediment grains act as long-term radiation dosimeters when shielded from further light

exposure with the luminescence signal a measure of radiation exposure during the burial period. The radiation dose that

$$\text{OSL age (year)} = \frac{\text{Equivalent dose (D}_e\text{; grays)}}{\alpha D_\alpha w + D_\beta w + D_\gamma w + D_c} \quad (1)$$

α = *alpha efficiency* (0.03–0.15) for grains
>50 μm = 0

D_α = alpha dose

D_β = beta dose

D_γ = gamma dose

D_c = cosmic dose

w = attenuation by water

is equivalent to the natural luminescence emission of isolated quartz and feldspar grains is referred to as the equivalent dose (D_e , measured in grays: 100 rads = 1 gray) and is one half of the OSL age equation (Eq. 1). In most dating applications, quartz is often the favored mineral because of its abundance in sediments, ease of physical separation, and known stability of luminescence emissions. In contrast, feldspar minerals are often less abundant and have a troubling signal instability (anomalous fading), though yield considerably brighter OSL emissions. The recent development of charge transfer techniques for potassium feldspar (e.g., post IR290) that use elevated preheats (~290 °C) to transfer electrons from stable deeper to shallower traps for ease of measurement has extended dating possibilities to 10^5 – 10^6 timescales for well solar-reset grains (Duller and Wintle 2012). Similar protocols have been also developed for quartz that has been particularly useful for dating Pleistocene loess deposits (e.g., Brown and Forman 2012).

A common approach in OSL dating is to use SAR protocols on quartz aliquots with the protocols customized for a specific sample, study site, or area (Fig. 2). The SAR approach is predicated on a number of assumptions. First, the fast component of luminescence emissions, light released within the first 4 s, is the dominant

signal, usually >90 % of the total light output above background levels. Second, the zero dose ratio is <5 % of the natural ratio. Furthermore, the natural ratio is not at dose saturation that errors in calculating aliquot or grain equivalent doses are ≤ 10 % and the recycling ratio is between 1.1 and 0.9, a measure of the coincident of the first and the last same regenerative dose and indicative that the test dose compensates well for sensitivity changes (Murray and Wintle 2003). A critical practice in luminescence dating is the application of preheats (160–260 °C) to isolate a stable and a time-indicative luminescence emission (Fig. 2). The accuracy of the SAR protocols is evaluated by applying a known dose and testing for specific heat treatments within a sequence of analysis (Fig. 2) if the known dose can be recovered. Often such tests indicate that the known dose can be recovered using a variety of preheat treatments. In practice, using the SAR protocols to determine an equivalent dose involves calculation of a ratio between the natural luminescence and the luminescence from a known test dose (L_n/T_n ratio), which is compared to the luminescence emissions for regenerative doses (L_x/T_x) and also divided by the luminescence from the same test dose (Fig. 2). Applying a known test dose with each measurement cycle provides a metric to correct for changes in the sensitivity of the dated quartz grain(s) to acquire luminescence. Often with each successive measurement cycle, the luminescence output increases by 5–15 % or more from the same radiation dose.

The equivalent dose using the SAR protocols is determined often on >30 aliquots of quartz or feldspar grains. Each aliquot often contains 10–100s of quartz grains, the total number dependent on grain size (e.g., 100–150 μm), plate area, and luminescence yield. Statistical analyses of equivalent dose distributions are critical to render accurate OSL ages with specific age models (Galbraith and Roberts 2012). A common metric used is an overdispersion percentage of a D_e distribution and is an estimate of the relative standard deviation from a central D_e value in context of a statistical estimate of errors. A zero

overdispersion percentage indicates high internal consistency in D_e values with 95 % of the D_e values within 2σ errors, though rarely, if ever is a naught value calculated with equivalent dose data. Overdispersion values $\sim \leq 20$ % (at two sigma errors) are routinely assessed for quartz grains that are well solar reset, like eolian sands (e.g., Olley et al. 2004; Wright et al. 2011), and this value is considered a threshold metric for calculation of a D_e value using the central age model of Galbraith and Roberts (2012). Overdispersion values >20 % may indicate mixing of grains of various ages or the partial solar resetting of grains, though overdispersion values up to 32 % have been associated with a single equivalent dose population, particularly if the equivalent dose distribution is symmetrical (Arnold and Roberts 2009). The minimum or maximum age model may be an appropriate statistical treatment for equivalent dose data that is positively or negatively skewed (Galbraith and Roberts 2012), depending on the pedologic and the sedimentologic context. The net effect of pedogenesis and bioturbation is often the mixing in of younger grains, and thus, a maximum age model may be appropriate (Ahr et al. 2013). In contrast, high-energy fluvial and colluvial depositional environments often incorporate partially solar-reset grains; thus, the minimum age model may be appropriate. Other numeric treatments such as finite mixture modeling may also be applicable for separating multiple populations of equivalent dose (Galbraith and Green 1990). The efficacy of these numeric analyses for isolating grain populations should be questioned, and independent tests of accuracy are advised.

Another advantageous approach in OSL dating is single-grain dating using the SAR protocols (e.g., Duller 2008, 2012). Dating single grains of quartz and feldspar is particularly suitable with a mixture of grain populations in sediments, a common occurrence in some fluvial and colluvial sedimentary environments. A significant challenge with single-grain dating is that often 1000s of quartz grains need to be analyzed because 20–90 % of the grains yield little or no luminescence emissions. Thus, a single age

determination can occupy a luminescence reader for weeks to months to render sufficient number of analyses to statistically separate equivalent dose populations. Though this approach is time consuming, highly credible data is generated for identifying different equivalent dose grain populations and ultimately accurate ages.

A determination of the environmental dose rate (grays/ka) is needed to render an OSL age (Eq. 1), which is an estimate of the exposure of mineral grains to ionizing radiation from the decay of U and Th series, ^{40}K , and cosmic sources during the burial period. The U, Th, and ^{40}K content of the sediments can be determined by elemental analyses by neutron activation analyses or inductively coupled plasma-mass spectrometry, though such analyses assume secular equilibrium in the U and Th decay series. A suitable alternative is either gamma spectrometry in the field or in laboratory; the laboratory variant (germanium gamma spectrometry) can detect isotopic disequilibrium in the U and Th decay series. If disequilibrium is detected, the dose rate should be suitably modified. The beta and gamma doses should be adjusted according to grain diameter to compensate for mass attenuation (Fain et al. 1999). There is no appreciable alpha dose for coarse grains ($>50 \mu\text{m}$) with the outer 10–20 μm of grains etched by soaking in HF during preparation. Fine grain sediments ($<40 \mu\text{m}$) are fully affected by alpha radiation. A cosmic ray component must be included in dose rate calculations which compensates for geographic position, elevation, depth of burial, and density of burial material (Prescott and Hutton 1994). An estimate of the moisture content (by weight) during the burial period is also needed for age calculation. Often estimating moisture is difficult because there are few sedimentologic or diagenetic criteria to quantify changes in moisture content during the burial period. Thus, realistic moisture contents are usually derived from particle size considerations, measured moisture contents in an undisturbed setting, evaluation of sediment compaction, level of water table to sampling site, and climatic conditions; and appropriate uncertainty (10–20 %) should be included.

Sedimentologic Context for OSL Dating

There are a number of sedimentary facies in tectonic settings that can be or have the potential to be dated by luminescence. A luminescence age for clastic sediment is a measure of the time since the last sunlight exposure. The zeroing of luminescence in mineral grains, usually by sunlight, must be related to a significant tectonic event, like burial of soil with sand-blow emplacement or colluviation post faulting, for the OSL age to be meaningful. In turn, dating sediments that were displaced or deformed provides maximum limiting ages on tectonic activity (e.g., Chen et al. 2013). Eolian sediments, like loess, sand sheet deposits, dune sands, and cover loams, are the most preferred sediments for OSL dating because of the long (hours) light exposure prior to deposition. Also, littoral and sublittoral sediments often receive long light exposure within the swash zone (Argyilan et al. 2005), though storm beach deposits may be variably solar reset.

Mineral grains in water-lain environments such as glacial-marine, certain lacustrine, and fluvial can be incompletely solar reset reflecting attenuation of spectra as light penetrates a turbid water column. Low-energy fluvial sediment, like shallow channel fills with millimeter-scale, horizontally bedded, medium sands, is the preferred facies for OSL dating (Schaetzl and Forman 2008). Higher-energy facies with erosion of previous deposited sediments and formation of new grains with clast percussion during saltation and creep at the base of the water column often yield a mixture of apparent grain ages. Colluvial and alluvial sediment, often associated with normal and reverse faulting, may be amenable for OSL dating, though care is needed to avoid sampling intraclasts in proximal colluvium, closest to the fault zone. Proximal colluvium is difficult to date by OSL and yields often highly dispersed equivalent dose values by aliquots and single grains, necessitating the use of finite mixture models (e.g., Cortes et al. 2012). Distal colluvium, deposited by grain transport with overland flow downslope of the fault offset, can be well solar reset and is more suitable for OSL dating (Forman

et al. 1989; Sohbati et al. 2012). There is some promise in OSL dating of minerals from fault gouge to constrain the timing of tectonic activity, though luminescence characteristics are highly variable (Spencer et al. 2012; Banerjee et al. 1999).

Weathered horizons exhibiting pedogenic accumulations of clay, silt, carbonate, or silica should be avoided scrupulously for OSL dating. Postdepositional pedogenesis can affect detrimentally the luminescence time signal by altering the radionuclide concentration, disrupting crystal structure, and mixing in fully or partially solar-reset grains and thus increasing overdispersion values (Ahr et al. 2013).

A detailed study of luminescence characteristics of quartz grains in soils indicates that the upper (<5 cm) part of A horizons in well-developed soils (e.g., alfisols) is well solar reset and is another target for OSL dating, particularly in the buried context (Ahr et al. 2013).

Sampling of Sediment for OSL Dating

Sampling sediment for luminescence dating is relatively straightforward, though care should be exercised that the appropriate sedimentary facies is sampled. It is critical that the sedimentologic, pedologic, stratigraphic, and tectonic context is well known prior to sampling, so a judicious decision is made on sample selection that weighs the likelihood of solar resetting with original deposition, minimizes pedogenic alterations, and maximizes that the sediment-depositional (OSL) age closely constrains tectonic activity. Ideally, at the sampling site, at least 20 cm of homogenous sediment should surround the collected sediment to maximize uniformity in the dose rate environment during the burial period. Sampling within 20 cm of boulders or major lithologic contacts should be avoided to obviate potential inhomogeneities in radioactivity. If such inhomogeneities cannot be avoided, field gamma spectrometry or collection of sediment from the disparate units is advised to document the in situ dose rate. Also, care should be

exercised in collection samples within 1–1.5 m of the surface, with likely pedogenic alterations. Approximately 30 g of sediment should be collected, though more or less sediment may be adequate depending on the concentration of the chosen particle size for dating. The geological luminescence signal of sediment is reduced rapidly with exposure to sunlight; thus, care must be taken not to expose the sediment to any light during sampling. The OSL signal of quartz is significantly reduced with a few seconds of light exposure. Prior to sampling, the section should be excavated back at least 20 cm to expose a fresh face. Immediately prior to sampling, the face should be scraped free of light-exposed grains on the surface. It is best to take the sediment intact; though the outer mineral grains may have been light exposed, the internal grains have been shielded from sunlight. The most efficacious approach for sampling for OSL dating is to use light-tight sediment coring tubes, composed of aluminum, copper, steel, or black, stiff plastic, like ABS. The tube should be 10–20 cm long, 2–4 cm diameter, and with an end cap, the tube can be hammered or pushed into the desired sediment for dating. For clay-rich or indurated sediments, blocks can be carved from the section and placed in Kubiena tins or other metallic containers. A secondary bag sample of sediment (~50 g) that can be light exposed should also be taken from a 20 cm radius from the tube/block collection point for elemental (dose rate) and particle size analyses.

Summary

Optically stimulating luminescence is a technique that dates the burial time of quartz and feldspar grains. The zeroing mechanism is the exposure of grains to >1 min of sunlight, and there is subsequent signal acquisition with burial, shielding from sunlight, and exposure to ionizing radiation, mostly from radioactive decay during the burial period. Specific minerals, like quartz and potassium feldspar, are dated, with a known particle size range (e.g., 100–150 μm) either as

aliquots (10–100s of grains) or single grains. In many sedimentary environments, like eolian, sublittoral, and littoral, mineral grains are well solar reset and are most amenable for OSL dating. However, in certain fluvial, colluvial, and alluvial environments, solar resetting of mineral grains is partial, or older grains are incorporated, and thus, there are often multiple populations of grain ages. The collection of unsuitable samples for OSL dating can be obviated by a careful sedimentary facies analysis that maximizes for light exposure of grains with transportation and deposition. In turn, there are a variety of computational solutions for single aliquot data to isolate grain populations that may be temporally significant, though the efficaciousness of such solutions should be questioned. Single-grain analyses, though laborious requiring the analyses of 100–1000s of grains, provide the needed analytical data to define grain populations and accurate ages.

The effective age range of OSL dating of quartz is ca. 100,000 years, though this limit will vary by ca. ± 50 ka with environmental dose rate and electron trap, stability density, and energy. Thermal transfer techniques may extend the dating of quartz and feldspar grains from well solar-reset sediments to 10^5 – 10^6 time-scales. OSL has wide application in tectonic settings in dating fault offset or uplifted sediments or sediment deposition that closely precede or succeed a faulting event. Judicious application of OSL dating is hinged on documenting the complex sedimentologic association with fault movement and understanding equally if not more complex the luminescence emissions from grains of quartz and feldspar which yield a time signature.

Introduction

This entry deals with the box behavior of masonry structures, which is a major hypothesis for the application of seismic assessment procedures based on the in-plane response of the walls, when using performance-based approaches for seismic safety. A general description is also made of the unreinforced and confined masonry building typologies, regarding the constructive technique, industrial development, and applicability. Methods and procedures are presented for the seismic assessment and safety verification of masonry buildings, which are applied to the case of a dwelling.

Masonry has been continually used for building, employing very different materials and bond patterns, but the main distinction between masonry constructions probably is the presence

or absence of rigid floor diaphragms well connected to the walls. According to this aspect, masonry constructions can be divided in two categories: structures with and without box behaviour, which present a very dissimilar response when subjected to seismic actions. For the case without box behavior, the walls of the building behave independently and out of phase, with combined in-plane and out-of-plane deformations, and presenting mainly out-of-plane damage (Fig. 1a). On the other hand, when with box behavior the building acts as a jointly assemblage of walls and roofs, with mainly in-plane response of the walls (Fig. 1b).

The concept of box behavior was a key assumption of methods developed for the seismic analysis of masonry structures, e.g., the POR (Tomažević 1978). In this case, a macroelement discretization has been adopted for the walls through a frame-type assemblage of pier, spandrel, and connection elements (Marques and Lourenço 2011). For the POR, it was initially considered that the walls deform jointly and without plane rotation, thus the global response of a masonry structure being computed as the sum of the in-plane response of individual walls. Within this hypothesis, even if the masonry is a brittle material, the variety of wall sections (deformation capacities) in a building allows a significant structural ductility.

These methods consider generally an elastic–perfectly plastic load–displacement response for the walls according to given strength

Masonry Box Behavior, Fig. 1 Illustration of box behavior concepts (Adapted from Touliatos 1996): (a) out-of-plane failure, (b) in-plane response due to box behavior

criterion and ultimate drift, depending on the formed collapse mechanism by shear or flexure. The response of the building is then evaluated by a pushover loading analysis, which allows identifying the sequence of damage events on panels, reflecting in a graphical representation of the base shear force against the displacement of a control point, e.g., the centroid of the roof slab, which is called the capacity curve. This curve is an intrinsic feature of the building that reflects, beyond the base shear strength and deformation capacity, the dissipated energy.

The concept of box behavior and the current performance-based approaches for seismic assessment specified in codes (e.g., EN 1998-1 2004; Sullivan et al. 2012) are explained here referring to cases of unreinforced and confined masonry building structures. In the next two sections, these typologies are presented in general terms.

Unreinforced Masonry

Unreinforced masonry is an ancient, traditional, and ongoing construction typology, whose system consists in the juxtaposition and superposition of masonry pieces through joints. In the antiquity, stone pieces and mud bricks were used for the construction of unreinforced masonry monumental buildings, but the great revolution of this construction technique was with the production of burnt clay bricks. In recent years, a large development was verified in the industry of ceramic bricks allowing for high

quality and efficiency, regarding mechanical properties and functional aspects of the brick itself and of the masonry components as an assemblage. At the same time, concrete and calcium silicate blocks were also developed, which are an alternative to ceramic bricks. Masonry requires also for a good quality of remaining constituents, particularly the joint mortar. Block masonry systems have been also developed with mortar pocket and/or tongue-and-groove head joints, e.g., in Fig. 2. Aiming to control cracking due to creep and shrinkage movements, bed-joint steel truss reinforcement is in many cases recommended.

Unreinforced masonry is widely used in Germany (mainly ceramic brick masonry, e.g., Jäger et al. 2010) and in Brazil (mainly concrete block masonry, e.g., Parsekian et al. 2012), which demonstrates the wide applicability of unreinforced masonry around the world, both in cases of strong-economy nations and developing countries. In these countries, great development was observed with the industrialization of, more than a masonry unit, a masonry system allowing for a modular design with use of complementary pieces, such as half bricks, corner blocks, lintel bricks, etc. Masonry systems need to consider also for functionality regarding the installation of water supplies and cable networks, namely, through driving of shafts into the walls. Another aspect to consider is the adequacy of used solutions for slabs, particularly concerning the condition of box behavior. Regarding this point, solutions need to be considered that allow an effective connection of the

Masonry Box Behavior, Fig. 2 Example of an unreinforced masonry system: (a) building view, (b) scheme of the bond

walls to the slab system, namely, through the use of a bond beam.

Even if the constructive process of masonry is very simple, skilled labor is a major aspect for unreinforced masonry construction, since the practices for infill walls have caused a great degradation of the masonry works, which requires for a re-specialization. Once more, the architectural trends and requested esthetics for buildings are a great challenge for masonry as a material and for engineers, when requiring for asymmetric, complex, and irregular configurations. For this reason, more than other construction typology, unreinforced masonry requires a much synchronized planning involving both architects and engineers to allow the feasibility of the construction. However, unreinforced masonry presents a restricted applicability in high seismicity regions due to limited earthquake resistance, in which cases an improvement to the masonry system is necessary, namely, by using the confined masonry typology presented in the next section. Reinforced masonry is also an alternative, which is largely disseminated in the United States and Canada (Parsekian et al. 2012), but which implementation seems not easily and directly adaptable to other countries.

Confined Masonry

Confined masonry was historically introduced as a reaction to destructive earthquakes in Italy and

Chile (1908 Messina and 1928 Talca quakes, respectively), which almost completely destroyed traditional unreinforced masonry buildings. The improvement of this technique was reflected on the good performance of confined masonry buildings subjected to the 1939 Chilean earthquake, which was probably the main reason for the large dissemination of this technique in all Latin America (Brzev 2007). The construction with confined masonry spread widely to all continents, in countries with moderate-to-high seismicity such as Slovenia, India, New Zealand, Japan, and Canada.

Conceptually, the confined masonry system is based on embracing masonry panels with frame elements, similarly to reinforced concrete frames, but with the difference that in the confined masonry the reinforced concrete elements are cast only after the masonry construction (Fig. 3a). For this reason, contrarily to reinforced concrete structures where infill masonry is built after concrete hardening, in the case of confined masonry most of the building weight rests on the masonry panels. In addition, due to concrete shrinkage, the connection between masonry and concrete is very effective (Fig. 3b). The interaction between the confining elements and the masonry panel allows a confined masonry wall under lateral loading to behave as a whole up to large deformation levels, allowing improved strength and ductility (e.g., Gouveia and Lourenço 2007). A typical phenomenon in confined masonry is the dowel

Masonry Box Behavior, Fig. 3 Illustrations of confined masonry typology: (a) construction example (Courtesy of Paulo B. Lourenço), (b) difference between infill and confined masonry regarding the frame-to-masonry connection

action of the longitudinal reinforcement bars of the concrete columns, which balances the loss of shear strength in the masonry panel, allowing to keep the strength necessary for a ductile response.

In practice, and relatively to the reinforced concrete system, confined masonry allows normally for economical savings due to the required smaller sections of concrete and steel. However, even if extensive experimental studies have been performed to evaluate the shear response of confined masonry structures (e.g., San Bartolomé 1994), the practice of self-construction and the use of prescriptive rules have led to poor earthquake resistance. Additionally, the use in many cases of poor-quality units leads to its break and to an inadequate behavior of the confined walls. The observed seismic damage in confined masonry buildings occurs in some cases at upper stories of the buildings, with associated out-of-plane damage, and is mostly due to the absence of box behavior in the affected stories. Brzev et al. (2010) attribute the seismic damage on confined masonry buildings mainly to inadequate wall density, poor quality of masonry and construction, deficiencies in detailing of reinforced concrete confining elements, absence of confinements at openings, and geotechnical issues.

In Europe, industrialized systems for confined masonry have been developed, namely, in Spain and Portugal, which allow for a modular design (e.g., Lourenço et al. 2008). An important aspect in the case of confined masonry is the formation of thermal bridges due to masonry discontinuity,

whose problem can normally be solved by coating the columns with thermal insulation plates or by casting the piers within special blocks. This construction typology is also a potential solution for the problem of housing in developing countries due to its quick construction and economy. Confined masonry was, for example, used in the reconstruction of Haiti after the 2010 earthquake.

Macroelement Models

Masonry structures present specific and diverse bond typologies, for which several modeling approaches have been adopted. In the academic-research field, the modeling of masonry buildings has been applied using two different scales, namely, the finite element and macroelement approaches (Lourenço 2002). The concept of using structural component models for masonry structures, designated by macroelement modeling, was introduced by Tomažević (1978) and applied to perform seismic assessment. This concept is the one addressed next, given the easy implementation of material laws and the formulation of structural equilibrium. In addition, the adopted structural component discretization largely reduces the number of degrees of freedom in relation to the traditional finite element modeling approaches, allowing for more resource- and time-efficient computations and making them attractive to practitioners. In the following, the available models are briefly described for unreinforced and confined masonry.

Masonry Box Behavior, Fig. 4 Schematization of wall models in (a) SAM II, (b) TreMuri, and (c) 3DMacro

Recently, and mainly in Italy, several user-friendly computer codes based on macroelements have been developed for assessing the seismic safety of unreinforced masonry buildings. Marques and Lourenço (2011) benchmarked the ANDILWall/SAM II (Calliari et al. 2010), the TreMuri (Lagomarsino et al. 2009), and the 3DMacro (Gruppo Sismica 2013) software codes and provided the basic description of the macroelement formulation and assemblage used in these methods. Briefly, SAM II and TreMuri are based on frame-type modeling by using one-dimensional macroelements, while the 3DMacro is based on a discretization with two-dimensional discrete elements, as shown in Fig. 4. The seismic assessment is made through performance-based approaches, i.e., procedures for nonlinear static (pushover) analysis, according to recent design codes (EN 1998-1 2004; Sullivan et al. 2012).

The methods above were developed throughout a sequential process, including first the idealization of the macroelement, then the definition of the wall assemblage, and finally the simulation of the full building model. The validation process of these methods was made by referring to experimental testing and more advanced computations, for individual masonry panels, full plane masonry walls, and three-dimensional structures, e.g., for the building tested by Magenes et al. (1995). This validation process is not easy due to the large variability of masonry materials and due to the importance that the complex structural organization in full buildings might assume.

On the other hand, rather few quasi-static tests on unreinforced masonry buildings have been carried out allowing this validation. Many unreinforced masonry building models have been tested in shaking tables, but, in general, the dynamic experimental behavior is difficult to compare with the pushover response.

Confined masonry is a particular case of masonry structures, even if it presents some similarity with reinforced concrete structures because of the presence of a frame. Confined masonry is characterized by casting of the reinforced concrete elements only after the masonry work, which provides a good connection between the confining elements and the masonry panels due to the combination of bond effects, shrinkage of the reinforced concrete elements, and the fact that the vertical dead load is transferred to the walls. The interaction behavior between the confining elements and masonry through the existing interface is a specific aspect that needs to be considered in the response of confined masonry walls under lateral loading. Some models have been implemented for confined masonry structures based on a wide-column approach (e.g., (Marques and Lourenço 2013), considering the interaction behavior between the confining elements and the masonry implicitly in the wall shear response.

Micro-modeling strategies can also be used for confined masonry, namely, based on the finite element method, to model explicitly the concrete–masonry interface (e.g., Calderini et al. 2008). Alternatively, a discrete element

Masonry Box Behavior,
Fig. 5 Discrete
 macroelement: (a) interface
 model, (b) frame element,
 and (c) example of
 interaction domain
 N – M_x – M_y

approach is also applicable, such as that idealized by Calìo et al. (2012) originally for unreinforced masonry and which has been extended in the 3DMacro software (Gruppo Sismica 2013) to model reinforced concrete/steel/masonry mixed structures. This last approach uses an interface connection (constituted by nonlinear springs) between the masonry panels (Fig. 5a), which in the case of two neighboring confined masonry panels is interposed by a frame modeled through nonlinear beam finite elements with concentrated plasticity (Fig. 5b). For the beam elements and in agreement to a given type of interaction (axial, flexural, or axial-flexural), the corresponding hinges are considered according to the respective N – M_x – M_y domain (such as in Fig. 5c).

Nonlinear Static (Pushover) Analysis

The first approaches for seismic analysis were based on the concept of seismic coefficient, which represents the proportion of the building weight that is applied as a lateral force to the structure. Later, approaches were introduced

considering the response in displacements of the masonry walls, accounting for the greater sensitivity of the damage to the imposed displacements (e.g., Turnšek and Čačovič 1970).

The masonry structures can present significant ductility when subjected to lateral actions, which is the greater the higher the ductility of sections and the larger the variety of wall geometries (deformation capacities). This concept is early evidenced from damage patterns observed in masonry buildings subjected to earthquakes (e.g., 1963 Skopje, 1965 Oaxaca and 1976 Friuli earthquakes) and also based on experimental evidence (Tomažević 1999). The masonry walls show a great capacity of inelastic cyclic deformation and energy dissipation due to progressive activation of damage mechanisms. Furthermore, the walls are capable to support the vertical loading even if significantly damaged (e.g., with diagonal cracks).

The study of the nonlinear behavior of structures was started in the 1960s for reinforced concrete, particularly based on the observation of earthquake-damaged buildings. Later, numerical models were developed for the nonlinear static

Masonry Box Behavior, Fig. 6 Illustration of the pushover analysis on a masonry building

analysis of reinforced concrete structures (Saiidi and Sozen 1981). A similar investigation sequence and line time was observed for masonry structures (Tomažević 1978). However, if for the case of reinforced concrete structures advanced models were proposed in the background of extensive resources and studies, the proposed methods for masonry were simpler. This was due to the secondary role of masonry structures in the construction sector and particularly to the very complex behavior of masonry.

The nonlinear static analysis, or pushover analysis as popularized, is focused on the evaluation of the seismic performance of structures based on the control of damage mechanisms and deformation. Several procedures for pushover analysis have been developed, which allow considering the inelastic reserve of capacity in the design and safety verification of structures as a simplified alternative to the nonlinear dynamic time history analysis, e.g., the N2 method (Fajfar and Fischinger 1988) specified in seismic codes (EN 1998-1 2004; Sullivan et al. 2012). The procedures for pushover analysis are based on the control of deformation, where the displacement demands due to the design earthquakes are obtained through a spectral analysis of the response of an equivalent single-degree-of-freedom system, which are after compared with the displacement capacities corresponding to given performance levels.

The displacement capacities are computed from the capacity curve obtained for the building, which presents the evolution of the base shear force (horizontal force representative of the seismic action) against the displacement of a control point (significant point of the structure, usually the centroid of the roof slab), e.g., in Fig. 6. This curve is computed by applying an incremental lateral static loading on the structure, which is processed with force and/or displacement control, and for which two load distribution patterns are usually assumed: proportional to the inertial masses multiplied by the displacements of the first vibrational mode of the structure (modal distribution) and proportional to the inertial masses (uniform distribution).

Seismic Safety Assessment

Traditionally, the seismic design of buildings is based on computing a solicitation for the structure in terms of a base shear force through the consideration of a seismic coefficient or spectrum, which is reduced by a behavior factor and distributed after to the structure. However, the behavior factor values recommended in Eurocode 8 (EN 1998-1 2004) for masonry structures (1.5–2.0) turned out to be very conservative, and often the buildings are considered unsafe. In this case, the consideration of an overstrength

ratio that multiplies the basic value of the behavior factor is mandatory, which reflects the possibility of force redistribution between elements beyond the elastic limit (Magenes 2006). The values for the overstrength ratio are specified in the Italian code (IBC 2008) based on experimental and analytical evidences.

Currently, a transition stage from force-based to performance-based design is verified through the use of approaches that consider the ductility or displacement capacity of the structure. The displacement-based approach, which in effect provides a safety verification rather than an explicit design, is presently the more developed level of seismic safety assessment. In this case, performance is related to acceptable damage and damage to displacement. The N2 method (Fajfar and Fischinger 1988) specified in Eurocode 8 (EN 1998-1 2004) is the method considered here.

For the safety evaluation, the N2 method defines a bilinear representation of the capacity curve corresponding to an equivalent single-degree-of-freedom system. According to the Italian code (IBC 2008), this representation includes a first straight line that passes by the origin and intercepts the capacity curve of the actual system for a base shear force of 70 % of the maximum and a second line, horizontal and defined in mode that the area below the envelope of the actual system equalizes the area under the bilinear idealized response. The bilinear representation allows to obtain the reference period of vibration for the computation of the target displacement.

The procedure for safety verification is based on the evaluation of the seismic performance of the building, in terms of deformation, verifying that the target displacement is lower than the displacement capacity of the building, obtained on the capacity curve in correspondence with the established limit states. Commonly, damage and ultimate limit states are considered, which are, respectively, associated with the peak base shear and with a post-peak remaining base shear force of 80 %. A factor is also considered as the ratio between the elastic response force and the yield force of the equivalent system, which value

(imposed to be less than 3.0) represents a limitation to the ductility of the structural system as a whole.

The out-of-plane assessment is an issue not clearly evidenced in seismic codes, which implies a personal interpretation of safety from the engineer. However, in general, it can be considered that the control of slenderness limitations, minimum thickness requirements, and appropriate structural conception and detailing (rigid diaphragms and efficient floor-to-wall connection) avoid out-of-plane driven failures. A possibility to check the out-of-plane safety is the application of a kinematic limit analysis, which in effect has been implemented in several commercial software codes, additionally to the global displacement-based safety verification. In this case, the user needs to define the potential kinematic blocks (portions of connected walls), the kind of mechanisms, and respective hinges and constraints.

Application to Dwelling House

Dwelling houses up to two stories are the majority of the building stock in Europe, in terms of both existing and newly constructed buildings. The loss of masonry as a structural solution, due to an ungrounded perception of its lack of capacity to resist earthquakes and also to the dissemination of reinforced concrete structures, caused a strong reduction of the use of structural masonry in new buildings. On the other hand, a large development occurred in the masonry industry, namely, with the introduction of high-quality masonry systems regarding functional and mechanical features. In the academic field important efforts have been also made to develop adequate tools to account for the intrinsic nonlinear capacity of masonry structures when subjected to earthquakes. A first comparison of these tools was made by Marques and Lourenço (2011) referring to a simple building configuration. In this work the comparison is extended, concerning a real and more complex structure.

The studied two-story semidetached dwelling is representative of typical housing in southern

Masonry Box Behavior, Fig. 7 Architectural drawings of the dwelling: plans and elevation views

Europe, with rooms and kitchen in the ground story and bedrooms and an office in the first story. The house presents also a garage and a multilevel roof, as shown in Fig. 7. The structure of the building was originally designed in reinforced concrete. In the following, alternative to the original structure, solutions of unreinforced masonry and confined masonry structures are

presented and compared. The building is assumed to be constructed on type B ground (deposits of very dense sand, gravel, or very stiff clay).

Unreinforced masonry, considering that is a simple construction technique which allows an energy-efficient enclosure with no thermal bridges concern, is the first adopted option. In this case,

Masonry Box Behavior, Fig. 8 Structural plans of the constructive solution in unreinforced masonry

a clay block masonry system is used with tongue-and-groove head joints and with shell-bedded horizontal joints. The system uses a vertically perforated block of $0.30 \text{ m} \times 0.30 \text{ m} \times 0.19 \text{ m}$ and complementary pieces (half block, end piece, corner block, adjusting piece, and lintel block) allowing a geometry in plan with a module of 0.15 m . A M10 mortar pre-batched, according to Eurocode 6 (EN 1996-1-1 2005), is used for the joints. The plans for the proposed structure are presented in Fig. 8, which show the bond in the first course and the second course arrangement around the wall crossings.

The floors of the building are made with prestressed ribbed slabs, which have a thickness of 0.19 and 0.15 m in the accessible zones and for

the ceiling/roof, respectively. The slabs are similar to those used in the original reinforced concrete structure and are subjected to dead loads of 4.5 and 3.0 kN/m^2 and to live loads of 2.0 and 0.4 kN/m^2 for the same areas. A bond beam is made with the lintel block that serves as a formwork, with a concrete section of $0.20 \times 0.35 \text{ m}^2$ and reinforcement of $4\phi 10 \text{ mm}$ with stirrups $\phi 6 \text{ mm} @ 0.20 \text{ m}$ (0.10 m at the ends). The properties for the masonry were considered according to Eurocode 6 and the producer-declared values and selected materials, resulting in a compressive strength of 3.25 MPa , a pure shear strength of 0.1 MPa , an elastic modulus of $3,250 \text{ MPa}$, and a shear modulus of $1,300 \text{ MPa}$. Additionally, the in-plane ultimate

Masonry Box Behavior, Fig. 9 Geometrical and computational models of an unreinforced masonry building

drifts for the masonry panels were assumed, according to Eurocode 8 (EN 1998-1 2004) and the Italian code (IBC 2008) with values of 0.4 % and 0.8 %, respectively, for the shear and flexural failure modes. The weight for the masonry with plastering is 12.0 kN/m^3 .

The building was modeled in the macroelement software code developed by Gruppo Sismica (2013), according to the geometrical and computational models presented in Fig. 9. The floors are simulated as polygonal diaphragms elastically deformable, considering an orthotropic slab element. The model was analyzed under pushover loading in the principal directions, and considering “mass” and “first-mode” load distributions. Concerning the +X and +Y analysis with first-mode load distribution, the damage sequence for the building is shown in Fig. 10. For +X and regarding the front façade, a trend is captured in the ground story with shear failure of the central pier and rocking of the extreme piers and with concentration of displacements at this story. A similar deformation mechanism and substantial shear damage are observed in Fig. 10a for the other wall alignments. In +Y, rocking and shear failures are predicted for slender and squat panels, respectively, and identifying a first story mechanism.

A confined masonry solution was also considered following the prescriptive rules from the European regulations. For the confining columns, according to Eurocode 6 (EN 1996-1-1 2005), a longitudinal steel reinforcement must be included equivalent to 0.8 % of the column’s

cross-section area, with a minimum of $4\phi 8 \text{ mm}$. The transversal reinforcement consists of 6 mm diameter stirrups spaced in general of 0.20 m and of 0.10 m at the column ends. The solution for the horizontal confining element is the same adopted for the unreinforced masonry structure. The structural plans for the confined masonry solution are presented in Fig. 11. The confined masonry structure was also modeled in the software by Gruppo Sismica (2013) with the geometrical and computational models shown in Fig. 12. Note that the main change with respect to the unreinforced masonry model is the inclusion of the reinforced concrete confining columns, which are simulated as beam finite elements with concentrated plasticity and feature a tridimensional constitutive behavior $N-M_x-M_y$. The model was then analyzed under pushover loading in the main directions and assuming load distributions proportional to the mass and to the first vibration mode.

The damage sequence for the confined masonry model is illustrated in Figs. 13 and 14 for the +X and +Y analysis with “first-mode” load distribution, corresponding to different displacement levels. For both analyses, damage in the building starts to be relevant at 1 mm displacement, when several masonry panels develop tensile cracks in the interfaces and also diagonal shear cracking. For a displacement of 4 mm, damage spreads widely to all walls of the building. Then, damage evolves with increasing deformation due to the progressive formation of flexural plastic hinges at the ends of the confining elements.

Masonry Box Behavior, Fig. 10 Predicted damage sequence corresponding to the (a) +X and (b) +Y analysis (X diagonal shear, = tension cracks, • flexural plastic hinge)

The capacity curves for both unreinforced masonry and confined masonry structural solutions are compared in Figs. 15 and 16, where the base shear is expressed as a percentage of the building weight (%g). In X, the weaker direction, the unreinforced masonry building presents a base shear strength of about 23 % of the weight and a deformation capacity higher than 10 mm. Regarding the confined masonry solution, an increase of the base shear capacity is clearly observed for the X direction, comparatively to the unreinforced masonry solution. Still, a sharp decrease of capacity is found after peak due to a small number of confined panels and the absence of walls at the first story in the left part of the building. The high degradation of the

confined walls at peak load generates a ground story mechanism. Concerning the Y direction, a remarkable improvement of the base shear strength and ductility is observed.

Finally, considering that the building is subjected to a type 2 spectrum (“near-field earthquake”) in Eurocode 8 (EN 1998-1 2004), and from using the N2 method (Fajfar and Fischinger 1988) in the software code by Gruppo Sismica (2013), an evaluation is made of the values of the reference peak ground acceleration on type A ground (rock formations), $a_{g,u}$, corresponding to the ultimate displacement allowed for the building. These values are presented in Fig. 17, which can be considered as an indicator of the seismic performance of the structure. The $a_{g,u}$

Masonry Box Behavior, Fig. 11 Structural plans of the constructive solution in confined masonry

Masonry Box Behavior, Fig. 12 Geometrical and computational models of a confined masonry building

Masonry Box Behavior, Fig. 13 Damage sequence for the +X analysis with first-mode load distribution (X diagonal shear, = tension cracks, • flexural plastic hinge)

can be interpreted as the maximum ground acceleration supported by the building for a condition of near collapse or ultimate state, which can be directly compared with the design ground acceleration for a global safety verification.

Conclusions and Future Directions

Masonry constructions are, more than a legacy from the past, a solution for the future, given the existing development in the sector. The box behavior is a fundamental feature of masonry buildings, which allows the structures to present a significant ductility when subjected to

earthquakes. This ductility is reflected in the capacity of inelastic displacements for the masonry buildings, allowing them to support significant ground accelerations. Using a typical house in southern Europe as a case study, structural masonry typologies featuring box behavior allow ensuring seismic safety up to large ground acceleration levels, namely, 0.15 and 0.20 g for unreinforced masonry and confined masonry solutions, respectively.

The box behavior is then a request for earthquake-resistant masonry construction, which can be obtained through the adoption of slab solutions allowing for an enough diaphragm effect and good floor-to-wall connection.

Masonry Box Behavior, Fig. 16 Capacity curves in Y direction for the unreinforced masonry and confined masonry models

Masonry Box Behavior, Fig. 17 Evaluation of the maximum acceleration capacity of the building

The supply of box behavior needs also to be considered when retrofitting existing masonry buildings with flexible timber floors, e.g., through the adoption of a multi-plank system for the floors. The development of solutions to provide box behavior to social housing buildings in developing countries is also a problem that requires study. This is, for example, the case of traditional adobe masonry constructions in mountainous regions of Peru, which are usually covered with

lightweight wooden roofs poorly connected to the adobe walls.

Summary

Masonry box behavior is a feature of masonry structures that present floors significantly rigid and well connected to the walls. This is the case of new masonry buildings constructed with

a floor system of ribbed or reinforced concrete slab bonded to the walls by a ring beam, unlike existing buildings with timber floors. However, for this last case, a retrofit solution by stiffening the floor system and providing adequate wall-to-floor connections allows also a box behavior.

Nevertheless, the concept of box behavior is mainly applicable to current unreinforced and confined masonry buildings. The box action is a key assumption of macroelement methods developed for the seismic assessment of masonry buildings, when considering that the walls in a given direction respond jointly under lateral loading. Under this hypothesis, the seismic response of a building can be obtained through nonlinear static (pushover) analysis, i.e., submitting the building to an incremental static loading and considering the inelastic stage of behavior.

The pushover analysis provides the capacity curve (base shear force vs. displacement of the centroid of the roof slab) of the building, whose evolution depends on the sequence of cracking and failure events verified for the structure. The capacity curve is the reference to proceed with a performance-based seismic assessment, which is commonly based on the comparison of the displacement capacity and demand. Under this approach, the masonry box behavior normally allows the building to perform better when subjected to earthquakes.

This entry provides a review of current masonry typologies featuring a box behavior, and is explained with application to the seismic assessment of a dwelling house.

Masonry materials; Mechanical behavior

Introduction

Masonry is a nonhomogeneous material, composed of units and mortar, which can be of different types, with distinct mechanical properties. The design of both masonry units and mortar is based on the role of the walls in the building. Load-bearing walls relate to structural elements that bear mainly vertical loads but can serve also to resist to horizontal loads. When a structural masonry building is submitted to in-plane and out-of-plane loadings induced by an earthquake, for example, the masonry walls are the structural elements that ensure the global stability of the building. This means that the walls should have adequate mechanical properties that enable them to resist to different combinations of compressive, shear, and tensile stresses. The boundary conditions influence the resisting mechanisms of the structural walls under in-plane loading, and in a building, the connection at the intersection walls is of paramount importance for the out-of-plane resisting mechanism. However, it is well established that the masonry mechanical properties are also relevant for the global mechanical performance of the structural masonry walls. Masonry units for load-bearing walls are usually laid so that their perforations are vertically oriented, whereas for partition walls, brick units with horizontal perforation are mostly adopted.

As a composite material, the mechanical properties of masonry under different loading configurations depend on the properties of masonry components. The unit has an important contribution for the resisting mechanisms of masonry particularly in case of resisting mechanisms that are associated to crushing and tensile cracking of masonry. On the other hand, mortar joints acting as a plane of weakness on the composite behavior of masonry can control the shear behavior, which is particularly relevant in case of strong unit–weak mortar joint combinations. The mortar joints have also a central role on the flexural behavior in the direction perpendicular to the bed joints, as it is tightly controlled by the tensile bond adherence. In case of experimental characterization, flexural testing of masonry in the direction perpendicular to bed joints can even

Masonry Components,**Fig. 1** Example of a masonry unit: concrete block

be used as a means of obtaining the tensile bond strength.

Besides the review on masonry material components, it is important to present and discuss the most important mechanical properties of masonry assemblages, together with a discussion of the main parameters affecting the seismic performance of masonry under distinct loading configurations. Understanding the response of the basic masonry materials is essential for interpreting the seismic response of masonry structural systems.

Masonry Units

Masonry is a composite material composed of masonry units with a regular arrangement that are connected with mortar commonly at horizontal bed and vertical head joints. The interface between units and mortar represents in general an important role on the mechanical behavior of the composite material submitted to distinct types of loading.

The masonry units represent the fundamental material for the formation of the main body of the masonry structural element and can be made of distinct raw materials, namely, clay, mud, concrete, calcium silicate, and stone. However, the clay and concrete are far the most common raw materials used in structural masonry units.

The masonry units have commonly a rough rectangular shape, and the dimensions are defined

generally by the (length) $\times$ (height) $\times$ (width) and are laid usually according to the larger dimension (length). The length and height of the masonry units are usually multiples of 200 mm (nominal dimensions), including the 10 mm for the mortar thickness so that modularity of the structural elements can be achieved. The modularity is an important characteristic of masonry to make the construction technology and geometrical implementation of the structural elements (walls) with openings easier. The external vertical surface of the masonry units is known as the shell of the unit, and the walls perpendicular to the face are the webs of the units (Fig. 1). The top and bottom faces of the masonry units are known as the bedding areas.

The masonry units can be solid or have vertical and horizontal voids/perforations known as cores with smaller dimension and cells. Generally, solid units can have up to 25 % of perforations in relation to their gross area. For structural purposes, it is more common that concrete or clay bricks should have vertical perforations along their full height. The horizontally perforated brick units are more common for nonstructural purposes, namely, for masonry infill walls typically used in some south European countries. Examples of common masonry units are shown in Fig. 2. Clay units have generally a set of vertical cores with reduced area, whereas the concrete blocks commonly have large hollow cells, as seen in Fig. 2a. In vertical perforated units, the faces are called as face shells connected

Masonry Components, Fig. 2 Examples on different types of masonry units: (a) clay brick unit, (b) concrete block unit, (c) masonry unit with tongue and groove vertical joints, and (d) masonry unit with mortar pocket

by the internal solid parts called as webs. When the perforation does not go through the entire height of the unit, it is called a frog. This has usually a conical shape. Sometimes, the units have indented ends over the full height and are called as frogged ends. When it is intended to have dry vertical joints, without the addition of mortar, tongue and groove or interlocking systems are designed (see Fig. 2c). In this case, the out-of-plane resistance should rely on the combination of the bed joint resistance and on the tongue and groove system. Other times, the geometry of the units foresees the addition of mortar into vertical pockets (see Fig. 2d), where, depending on the geometry, different reinforcing systems can be added to improve the resistance of masonry to in-plane and out-of-plane loads.

The raw materials used in the manufacturing process of clay units are commonly surface clays (recent sedimentary formations) but shales formed from clays under pressure or fire clay, mined at deeper levels. All of these clays are equivalent in terms of silica and alumina compounds with different types of metallic oxides. The surface clays present a great variability, and in some cases, a mixture of clay of distinct locations can be used to reduce the variability. The material used in the concrete units is a dry concrete composed of Portland cement, stone aggregates, and water. It is also common to use other blended cements including blast-furnace cement and fly ash and inert fillers, considered commonly as by-products, aiming at reducing the percentage of Portland cement. In other instances, expanded clay aggregates are used to reduce the weight of

the concrete units. Additive such as pozzolanic materials and other workability agents can be also used. The calcium silicate units are composed of sand and hydrated lime.

Besides the raw materials, the production technologies used to produce the clay, concrete masonry, and calcium silicate units are very different. The clay units are normally extruded and fired at different temperatures, whereas the concrete units are produced in molds with a required geometry through a vibration and pressing process. The calcium silicate units are manufactured by pressing the mixture of sand and hydrated lime and then autoclaving them in order to produce a tightly grained unit.

Mechanical Properties

The most relevant mechanical properties of masonry units consist of the compressive strength, elastic modulus, and tensile strength. The mechanical behavior of the masonry assemblages depends greatly on the mechanical properties of the masonry units.

The compressive strength of the unit can be seen as a measure of its quality, and it is important for predicting the compressive strength of masonry assemblages. The compressive strength and elastic modulus can be obtained experimentally from uniaxial compressive tests according to the European standards. The compressive strength is calculated from the loaded area, which is the gross area (length) $\times$ (width) of the unit when the units are oriented in the same way as they are intended to be laid in a bed of mortar. In general, an average value is obtained from the experimental results, being possible to calculate

Masonry Components, Fig. 3 Details about compression behavior of masonry units: (a) typical stress–strain diagrams and (b) effect of loading direction on the compressive strength of units

the characteristic value and the corresponding normalized compressive strength of the masonry unit, f_b , by multiplying the average values by a coefficient taking into account the moisture environment of the curing conditions (oven dry as a reference) and also by the shape factor, accounting for the dimensions of the width and the length. The modulus of elasticity can be calculated as a secant modulus of elasticity between 0 % and 33 % of the compressive strength of masonry unit in the stress–strain diagram obtained from the uniaxial compressive tests. This property can be important if advanced modeling of masonry is required.

In case of modern clay and concrete masonry units, considerably high values of compressive strength can be achieved, being generally higher than the strength requirements for units to be used in seismic zones. It is common to have an average compressive strength higher than 10 MPa. It should be noted that the compressive strength of masonry units is different from the compressive strength of the raw material due to the effect of the shape and geometry of the units. In spite of attempts that have been made to obtain the complete stress–strain diagram of masonry units in compression, it is hard to obtain the post-peak branch of the stress–strain diagrams describing the high-rate crack damage progress of the units after the maximum load is attained (see Fig. 3a).

It should be also noticed that the compressive strength of the masonry units can differ significantly according to the loading direction, namely, in the directions perpendicular and parallel to the laying and in the direction perpendicular to the face. According to the work carried out by Lourenço et al. (2010), it was observed that compressive strength is considerably higher in the direction perpendicular to the bed joints, due to the orientation of vertical perforations, in comparison with when the direction is parallel to the bed joints. A reduction of more than 30 % in the normalized compressive strength obtained in the parallel direction to the bed joints was also found experimentally for concrete units, as seen in Fig. 3b. This difference is attributed mainly to the geometry of the masonry units with distinct arrangements of the internal perforations and cells. This results naturally in the different compressive behavior of masonry under compression for the different loading directions. The failure modes recorded in clay and concrete masonry units confirm its brittle character. In clay units with vertical perforation, it is common to observe cracking and splitting of the internal webs and shells. In case of concrete masonry units, the failure mode has a commonly pyramidal trunk (Gihad et al. 2007; Haach 2009) (see Fig. 4). The first cracks appear vertically in corners of the units.

Masonry Components, Fig. 4 Crack patterns of concrete blocks under uniaxial compression

With increase of the load, there was a tendency of the connection of vertical cracks by a horizontal crack in the upper region of the unit. This behavior can be explained by the lateral restrictions caused by the steel plates in top and bottom of the specimen, generating friction forces. This horizontal crack occurs because the upper part of the units slides over the pyramidal-trunk surface of rupture. In some specimens near the collapse limit, a vertical crack also appeared in the central region of the unit. The brittle failure mode of the masonry units can influence the seismic performance of the masonry under shear walls due to local failures determining the failure mode of the walls (Tomažević et al. 2006).

Mortars for Masonry

Mortar is a component of masonry, and it is used to bond individual masonry units into a composite assemblage. It has a central role in the stress transfer among units when masonry is loaded by promoting and more uniform bearing and avoiding stress concentrations that can result in the premature collapse of masonry. The mortar has also the role of smoothing the irregularities of blocks and accommodating deformations associated with thermal expansion and shrinkage. As pointed out by Vasconcelos and Lourenço (2009), the deformability of masonry is clearly influenced by the material at the bed joints. Very distinct pre-peak behavior was found by considering dry saw unit–mortar interfaces, rough dry joints, lime mortar, or dry clay resulting from sieving granitic soil. The mortar also influences the bond strength (tensile and shear) of the joints.

The mortars for laying masonry units and filling the vertical joints are commonly a combination of Portland cement, lime, sand, and water in specified proportions. The strength of mortars is controlled by the cement, and the workability is controlled mainly by lime and by the grading of the sand, as shown in Fig. 5a. The sand can be natural or artificial resulting from crushing stone. The size and grading of the sand particles influence both the plastic and hardened properties. More graded sand (increased variation of the size and distribution of particles) contributes to improve workability of mortars, which play a major role on the laying process of masonry units. The workability can also be improved through the use of additives like clay fillers and air entrainment. Mortar mixes can be defined by specific proportions of the compounds in volume or in weight of the cement or binder (cement and lime) content. For example, the mortar mix defined by the trace 1:2:9 (cement:lime:sand) by volume means that it has double the volume of lime in relation to cement and has sand with a volume nine times the volume of cement. It can be considered also that the mortar mix has three times more sand in volume than the total binder of the mixture (cement and lime).

Properties of Fresh Mortar

The knowledge about the fresh and hardened properties of mortar is fundamental in ensuring a good performance of masonry walls. The most important properties in the fresh state of mortars are the workability, air content, and setting time (rate of hardening).

The workability of mortars plays an important role on the construction process of masonry

Masonry Components, Fig. 5 (a) Grading curve for sand and (b) measurement of mortar flow

structures. Workability may be considered as one of the most important properties of mortar, and it is related to the process of laying masonry units, and, thus, it influences directly the bricklayer's work. On the other hand, it is important to mention that the quality of the workmanship can influence considerably the mechanical properties of masonry. A workable mortar is easy to adhere to the surface of the trowel, slides off easily, spreads readily, and adheres easily to vertical surfaces. The workability can be improved by the addition of air entrainment agents to the cementitious materials, enhancing also the durability. The addition of lime and the use of an appropriate curve grade for the sand influence also positively the workability of mortar (Haach et al. 2011). The workability is an outcome of several properties such as consistency, plasticity, and cohesion. Given that plasticity and cohesion are difficult to measure, consistency is frequently used as the measure of workability. The consistency is obtained experimentally by the flow table test, as shown in Fig. 5b. An acceptable value for workability for masonry construction ranges from 150 to 180 mm.

The water retention is the property of the mortar that avoids the rapid loss of the mixing water in the masonry units and to the air, and it plays a major role on the bond adherence of the mortar to the masonry units. The ability of the mortar to retain water is important to prevent the excessive stiffening of the mortar before it is used in the

laying of masonry units to ensure an adequate hydration of cement and to prevent the water from bleeding out of the mortar. The ability of the mortar to retain water is related to the masonry unit's absorption and should be higher for higher absorption units.

The setting time of fresh mortar relates to the hardening process of mortar. If the setting time is low, the mortar can extrude out of the joints as laying is carried out. If the setting time is high, the mortar placing on the joints can be difficult. The proper hardening rate of the mortar contributes for the adequate bond to the masonry units.

Properties of Hardened Mortar

The most important mechanical properties of hardened mortar are compressive strength and bond. The bond presents a central role, not only in the mechanical performance of masonry under different loading configurations (shear, tension), but it is also important for the durability of masonry.

The bond between mortar and masonry units develops through mechanical interlocking resulting from its adherence. The bond can in certain extent result also from chemical adhesion. Several factors influence the bond between mortar and masonry units, such as properties of masonry units, type of mortar, water–cement ratio, air content, workmanship, workability, and curing conditions. The initial water absorption of the masonry units should be compatible

Masonry Components, Fig. 6 Behavior of hardened mortar: (a) stress–strain diagrams and influence of the addition of lime in the compressive strength and (b) influence of the w/c ratio in the compressive strength

with a good workability and appropriate water retention of the mortar to avoid rapid absorption of the water by the units from the mortar, reducing considerably the water availability for the hardening. The roughness of the masonry units is also important, being enhanced by rougher surfaces of the masonry units. More workable mortars result in better penetration through the voids of masonry units, improving the mechanical interlocking between mortar and masonry units. The additives that are placed in the mortar mix to enhance the workability also contribute to the enhancement of the bond.

Although it is known that the mortar plays a major role in the deformation of masonry under compression, it has also some influence on its compressive strength. More deformable mortar, with lower modulus of elasticity, increases the deformability of masonry under compression. The compressive strength of mortar is also used as an indicator of the workmanship quality, being common to take some mortar specimens during the construction for posterior testing and comparison with the compressive strength required. The compressive strength of mortar is affected by several factors, such as the cement content, the addition of lime, and water–cement ratio. The cement gives the strength to mortar, and if it is replaced by a certain quantity of lime, the compressive strength reduces, as shown in Fig. 6a. Additionally, the compressive strength of mortar

is also strongly reduced by the increase in the water–cement ratio (w/c) (Fig. 6b).

Masonry as a Composite Material

The masonry is considered as a composite material composed of units and mortar and unit–mortar interfaces, and its mechanical behavior depends on the mechanical characteristics of the elements and also on its arrangements. The loading configurations to which masonry is subjected depend on the structural element to which it belongs.

Compressive Behavior

The compressive strength of masonry is the primary mechanical property characterizing its structural quality and is fundamental for structural stability in case of load-bearing masonry walls. Compressive behavior is also important when masonry is subjected to lateral loading because the in-plane behavior depends on the compressive properties of masonry, especially if flexural resistance mechanisms predominate (Haach et al. 2011). The finite element numerical analysis of masonry walls based on macro-modeling also requires the data regarding the mechanical behavior of masonry under compression and the key mechanical properties, namely, the compressive strength, elastic modulus, and

fracture energy. Masonry is a composite material made of units and mortar, so it has been largely accepted that its failure mechanism and resistance is governed by the interaction between the different components.

In case of hollow or solid units with full mortar bedding and when the mortar has lower compressive strength than the masonry units, the cracking paths and overall behavior are considerably controlled by mechanical properties of mortar and masonry units. As the mortar has generally lower modulus of elasticity than the masonry unit, it exhibits a trend to expand laterally within the mortar joints more than the masonry, being restrained by the masonry units. This interaction results in a triaxial compression state of the mortar and on a compression-lateral tensile state on the masonry units. This stress state results in the vertical cracking of the units, as seen commonly in the experimental testing of masonry. In case of masonry units with face shell mortar bedding, it is common to find vertical cracking along the webs of the units. This is related to the nonuniform stress distribution of stresses along the height of the unit and along the thickness of the masonry and to the principal tensile stresses mainly at the top and bottom of the units (Lourenço et al. 2010).

The typical stress–strain diagram describing the compressive behavior of masonry is shown in Fig. 7. The pre-peak behavior is characterized by nonlinearity beyond approximately 60 % of the peak stress, particularly in concrete masonry. The clay brick masonry tends to present a more linear elastic behavior with nonlinearly close to the peak load, achieving also higher values of the compressive strength. Almost no post-peak is usually recorded, which is associated with the brittle character of unreinforced masonry under compression. However, the post-peak behavior of masonry is dependent on the type of units and also dependent on the mortar used. Concrete masonry specimens built with lime-based mortar present slight lower strength than masonry prisms built with cement-based mortar. Additionally, higher deformations characterized the compressive behavior of masonry built with lower strength mortar. In this case, the ability

Masonry Components, Fig. 7 Typical stress–strain diagram of concrete masonry under compression

deformation after peak load is higher, enabling more ductile response of masonry under compression (Haach et al. 2014). The compressive strength of masonry is always higher than the compressive strength of mortar and lower than the compressive strength of masonry unit. However, the compressive strength of masonry units takes a central role on the compressive strength of masonry. Higher strength masonry units lead to higher strength of masonry. The relation appears to be linear in concrete block masonry (Drysdale and Hamid 2005).

The direction of compression of masonry units is also an important factor to take into account. Even if, in general, masonry is load in the direction normal to bed joints, in case of masonry beams and flexural walls (out-of-plane loading), the compression in the parallel direction to the bed joints is relevant for their mechanical behavior. The compressive strength in the parallel direction to the bed joints reduces considerably in relation to the compressive strength in the normal direction to the bed joints, particularly in

Masonry Components,

Fig. 8 Typical failure patterns that can develop in masonry walls under shear

case of hollow units as it depends on the geometry of perforations. In case of clay brick units with vertical perforation, the compressive strength in the parallel direction to the bed joints is about 30 % of the compressive strength of the units in the normal direction to the bed joints, resulting in the lowering of the compressive strength of masonry in this direction. The failure modes are also distinct, being the failure in the parallel direction more ductile.

Masonry Under Shear

The main resisting mechanisms that are characteristic of the response of the masonry walls submitted to combined in-plane loading are shear and flexure, which results in distinct failure modes (Fig. 8). In general, in squat walls, shear resisting mechanism predominates, and in slender walls, the flexural resistance mechanism plays the major role. Low pre-compression load levels are associated to flexural resisting mechanisms, and high pre-compression load levels are in general associated with the development of more dominant shear resisting mechanism. The shear resisting mechanism is associated with diagonal cracks in the alignment of the compressive strut related to the tensile stresses developed in the perpendicular direction of the strut. Diagonal shear cracking can occur with distinct patterns, namely, cracks developing along the unit-mortar interfaces or through both unit and mortar interfaces and through masonry units as a combination of joint failure or brick shear-tension

splitting. In diagonal cracking along the unit-mortar interfaces, the shear behavior of the bed joints plays an important role on the response of the walls.

Shear Behavior Along the Bed Joints

The influence of mortar joints acting as a plane of weakness on the composite behavior of masonry is particularly relevant in case of strong unit-weak mortar joint combinations. Two basic failure modes can occur at the level of the unit-mortar interface: tensile failure (mode I) associated with stresses acting normal to joints and leading to the separation of the interface and shear failure (mode II) corresponding to a sliding mechanism of the units or shear failure of the mortar joint. The preponderance of one failure mode over another or the combination of various failure modes is essentially related to the orientation of the bed joints with respect to the principal stresses and to the ratio between the principal stresses.

The shear behavior of mortar masonry joints is characterized experimentally based on direct shear tests by following the typical shear test configuration as shown in Fig. 9a. The typical behavior of mortar masonry joints under increasing shear load and constant pre-compression load is presented in Fig. 9b. The general shape of the shear stress-shear displacement is characterized by a sharp initial linear stretch. The peak load is rapidly attained for very small shear displacements. Nonlinear deformations develop in the

Masonry Components,
Fig. 9 Typical shear stress–slipping diagram of mortar masonry joints under shear

Masonry Components,
Fig. 10 Relation between shear stress and normal stress

pre-peak regime only very close to the peak stress. After peak load is attained, there is a softening branch corresponding to progressive reduction of the cohesion of the joint, until reaching a constant dry-friction value. This stabilization is followed by the development of large plastic deformations.

After peak load is attained, there is a softening branch corresponding to progressive reduction of the cohesion of the joint, until reaching a constant dry-friction value. This stabilization is followed by the development of large plastic deformations.

In case of moderate pre-compression stresses, for which the nonlinear behavior of mortar is negligible and the friction resistance takes the central role, the shear resistance of masonry bed joints is linearly dependent on the compressive

stress (see Fig. 10) and is given by the Coulomb friction criterion:

$$\tau = c + \mu\sigma \quad (1)$$

where c is the shear strength at zero compressive stress (usually denoted by cohesion) and μ is the friction coefficient or tangent of the friction angle. For dry joints, the cohesion is obviously zero. It should be kept in mind that the failure envelope given by Eq. 1 describes only a local failure of masonry joints and cannot be directly assumed as the shear strength of the walls submitted to in-plane horizontal loads (Mann and Müller 1982; Calvi et al. 1996). In any case, the shear bond strength of masonry joints assumes a major role on the shear resistance when it can be

Masonry Components,

Fig. 11 Dilation of shear mortar joints: (a) definition and (b) effect of vertical pre-compression on the dilation

described by the Coulomb friction criterion (diagonal cracking along the unit–mortar interfaces). The shear bond strength of masonry units can be seen as the initial shear strength used to calculate the shear strength according to the Coulomb friction criterion, as suggested by Eurocode 6 (2005).

The strength values, particularly the cohesion, are greatly dependent on the moisture content, porosity of the units, initial rate of absorption of the units, the strength and composition of mortar, as well as the nature of the interface (Amadio and Rajgelj 1991). More plastic mortar enhances shear behavior of joints by promoting better adherence. Binda et al. (1994) pointed out that when strong mortar is considered, the strength of the units can also determine the shear behavior of the joints. In case of hollow concrete masonry, the mortar placed on the internal webs contributes considerably to the increase of the shear strength as it increases the mechanical interlocking. This implies that a wide range of shear strength values may be pointed out for various combinations of units and mortar. Mann and Müller (1982) indicated a mean friction coefficient of approximately 0.65 on brick–mortar assemblages and a cohesion ranging from 0.15 MPa up to 0.25 MPa, depending on the mortar grade. From the results of direct shear tests carried out by Pluijm (1999), the coefficient of internal friction ranges between 0.61 and 1.17, whereas cohesion varies from 0.28 MPa up to 4.76 MPa, depending on different types of units and mortar.

Another important issue regarding shear tests is the dilatant behavior of masonry joints. The dilatancy represents the difference between the variation on the normal displacements of the upper and the lower unit, Δv , as a result of the variation of the shear displacement Δu (see Fig. 11). The opening of the joint is associated with positive dilation, whereas negative values of dilatancy represent the compaction of the joint. The dilatancy of rock joints is mostly controlled by the joint roughness. In conjunction with the cohesion and the friction angle, the dilatancy is also required as a parameter for micro-modeling of masonry. As pointed out by Lourenço (1996), dilatancy in masonry wall structures leads to a significant increase of the shear strength in case of confinement.

In-Plane Tensile Strength

The other approach for the shear resistance of masonry shear walls is based on the Turnšek and Sheppard (1980) criterion, which is based on the assumption that diagonal cracking occurs when the maximum principal stress at the center of the wall reaches the tensile strength of the masonry.

The stress state is calculated by assuming that masonry is an isotropic and homogeneous material, which does not correspond to its actual behavior, since tensile strength is dependent on the orientation of the principal stress regarding the mortar bed joints. For height-to-width ratios (h/l) higher than 1.5, from which walls can be

considered as a solid in the Saint-Venant sense, the tensile principal stress can be calculated by Eq. 2:

$$\sigma_t = \sqrt{\left(\frac{\sigma_0}{2}\right)^2 + \tau_{\max}^2} - \frac{\sigma_0}{2} \quad (2)$$

being the vertical stress considered as the average stress, σ_0 , calculated as the ratio between the compressive load (N) and the area (txl) of the walls $N/(txl)$, and the horizontal stress is negligible. This assumption was confirmed by using photoelastic analysis as reported by Turnšek and Čačovič (1971).

Considering that the maximum shear stress, $\tau_{\max}$, assumes a parabolic distribution, the horizontal shear force corresponding to the opening of shear cracks, H_s , is derived by Eq. 2, presenting the following expression:

$$H_s = \frac{f_t}{b} \frac{lt}{b} \sqrt{1 + \frac{\sigma_0}{f_t}} \quad (3)$$

where f_t is taken as the tensile strength of masonry. The variable b takes the value of 1.5 for walls with height-to-length ratios larger than 1.5. In case of height-to-width ratios (h/l) ranging between 1.0 and 1.5, the shear stress distribution deviates from the parabolic shape, and the horizontal normal stress becomes different from zero. In case of unreinforced masonry, this force is considered as the shear resistance when the failure mode corresponds to the cracking involving the cracking of units along the diagonal compression strut.

The in-plane tensile strength of masonry, f_t , can be obtained experimentally through diagonal compression tests by following the recommendation of standard ASTM E519 (2002). The tensile strength of masonry is calculated through Eq. 4, assuming that in the center of the panel, a pure shear stress state develops corresponding to the tensile strength to the maximum principal stress given by Eq. 4:

$$f_t = 0.707 \times \frac{P}{A} \quad (4)$$

where P is the vertical load applied and A is the horizontal cross section of the specimens. The shear deformation is calculated based on Eq. 5, where ΔH and ΔV are the deformation measured along the compression and tension diagonals and g is the width of the diagonal of the panel. The shear modulus is calculated by the ratio between the shear stress and the shear deformation (Eq. 6):

$$\gamma = \frac{\Delta V + \Delta H}{g} \quad (5)$$

$$G = \frac{\tau}{\gamma} \quad (6)$$

The typical failure mode found in current modern unreinforced masonry composed of regular units and submitted to diagonal compression load results from the opening of a stair-stepped crack along the unit–mortar interface developing in the direction of load. The crack is developed in the perpendicular direction to the tensile stresses, which means that it appears when the tensile stress in masonry is reached. The failure of unreinforced masonry occurs suddenly in very brittle style (see Fig. 12a).

According to Haach (2009), the non-filling of vertical joints appears not to significantly influence the crack patterns and failure modes of unreinforced masonry, even if it can clearly influence the shear strength of masonry. The mortar type also influences the tensile strength as it influences the tensile and shear bond strengths of masonry joints, particularly in case of cracks that develop along the unit–mortar interfaces. The tensile strength of units influences the values of the tensile strength when the crack passes through the units.

Flexural Strength

The flexural strength of masonry assemblages subjected to out-of-plane bending relates to the resistance of walls submitted to lateral loads from wind, earthquakes, or earth pressures. Depending on the boundary conditions and wall geometry, the bending can develop about vertical axis, about the horizontal axis, or about both directions. Thus, the tensile strength is referred to the

Masonry Components, Fig. 12 Details of diagonal compression tests on unreinforced masonry: (a) failure patterns and (b) typical shear stress–strain diagrams (negative values correspond to vertical strains)

Masonry Components, Fig. 13 Loading configuration for the experimental determination of the flexural strength of masonry: (a) geral scheme and (b) bending parallel and in the normal direction to the bed joints

direction of the tension that can develop in the direction normal to the bed joints, f_{tn} , or in the direction parallel to the bed joints, f_{tp} .

The flexural strength of masonry units can be obtained experimentally according to EN 1052–2 (1999), by considering a four-point load testing configuration (see Fig. 13a) being the load applied typically according to the scheme as shown in Fig. 13b to obtain the flexural strength in the parallel and perpendicular direction to the bed joints.

The unreinforced masonry under flexure is characterized by a very brittle behavior, which is associated with the localized central crack involving the failure of the unit–mortar interface and the units (see Fig. 14a). When the flexure

develops in the normal direction to the bed joints, usually the crack patterns develop along a bed joint (de-bonding of the mortar from the masonry unit). In flexure parallel to the bed joints, the usually observed crack patterns are (1) stepped cracks along the unit–mortar interface, when masonry is made with strong units and weak mortar joints, and (2) cracks passing through head joints and masonry units. The flexural strength in the perpendicular direction to the bed joints can be also taken as the tensile bond strength of mortar joints. The typical force–displacement diagram relating to the vertical load applied and the maximum displacement measured at midspan, presented in Fig. 14b, confirms the brittle nature of masonry under flexure.

Masonry Components, Fig. 14 Details about the flexure behavior of unreinforced masonry: (a) crack pattern in flexure in the normal direction to the bed joints and (b)

typical force–displacement diagram (direction parallel to bed joints)

After peak load has been attained, there is an abrupt reduction of the bearing capacity, meaning that the masonry loses almost all resistance with no increment of displacement. The pre-peak regime is characterized by an elastic range with only a small nonlinearity very close to the peak load.

The flexural strength depends on the type of mortar, especially on the resistance and tensile bond strength. Also here the workability of mortar plays a major role as the tensile bond strength depends on the adequate adherence of the mortar to the unit. The flexural strength depends also on the tensile strength of the masonry units, particularly when flexure develops in the parallel direction to the bed joints.

Brief Code Considerations

The compressive strength of masonry can be estimated through empirical formulas generally based on the results of experimental tests. European masonry code (Eurocode 6 2005) proposes Eq. 7 to estimate the compressive strength of masonry:

$$f_k = k_b^{0.7} f_m^{0.3} \quad (7)$$

where k depends on the type and shape of units and mortar at bed joints, f_b is the normalized compressive strength of the unit, and f_m is the characteristic compressive strength of mortar.

For hollow clay units of group 2 and general-purpose mortar, k is 0.45.

The modulus of elasticity of masonry can be determined based on the experimental results, generally by taking the tangent value at 1/3 of the compressive strength of masonry in the stress–strain diagrams or by considering the secant values in a range between 0.1 and 0.4 of the compressive strength. It can be also estimated from the compressive strength of masonry. According to Eurocode 6 (2005), the elastic modulus can be obtained from Eq. 8:

$$E = k_E f_k \quad (8)$$

where k_E is recommended to be 1,000.

On the other hand, the values of shear modulus, G , used, for example, in the calculation of the lateral stiffness of masonry walls, can be estimated by multiplying the modulus of elasticity by 0.4 (Eurocode 6 2005).

In terms of shear, the Eurocode 6 (2005) suggests that the shear strength of masonry is calculated through Eq. 9:

$$f_{vk} = f_{vk0} + 0.4\sigma_d \quad (9)$$

where f_{vk0} is the characteristic initial strength of masonry, obtained for zero compressive stress, and σ_d is the average normal stress.

The value of the characteristic shear stress should not be higher than $0.065f_b$ (f_b is the normalized compressive strength of masonry units) neither exceed f_{vlt} , which should be defined in the National Annex.

The values of the initial shear strength given in Eurocode 6 (2005) depend on the type of unit (clay, calcium silicate, concrete, stone) and on the type of mortar (general-purpose mortar, light-weight mortar, or thin-layer mortar).

The characteristic flexural strength of masonry can be obtained by experimental tests or alternatively through the values suggested in Eurocode 6 (2005), depending on the type of unit and type of mortar. Typically, the characteristic flexural strength in the direction normal to the bed joints ranges from 0.1 to 0.2 MPa, and the characteristic flexural strength in the direction parallel to the bed joints ranges from 0.2 to 0.4 MPa.

There are requirements for the masonry units and mortar to be used in earthquake-prone regions. In case of masonry units, the normalized compressive strength should be higher than 5 MPa in the normal direction to the bed joints and 2.0 MPa in the parallel direction to the bed joints. The recommended values for the compressive strength of mortar are 5.0 MPa for unreinforced masonry and 10.0 MPa for reinforced masonry (Eurocode 8 2004).

Summary

In this section, a review on the masonry components and on mechanical properties of masonry under distinct loading configurations has been made. Additionally, some code considerations about the design mechanical properties of masonry are provided.

The masonry units have a wide range of possibilities either from the viewpoint of raw materials or from geometrical configurations. The geometrical configuration should comply with thermal and mechanical requirements to optimize the performance both from the mechanical and physical point of view. Besides the strength, it is required that the mortar should present an

adequate workability and water retention ability so that an adequate mechanical behavior of masonry is attained. These properties play a major role on the bond strength of masonry (tensile and shear bond strength), which in turn have an important contribution on the shear and flexural resistance of masonry.

The compressive strength of masonry is clearly dependent on the mechanical properties of the components, the masonry unit being more important than mortar, which contributes mainly to the deformability of masonry. Depending on the failure patterns, which are dependent on the level of vertical load applied and boundary conditions, the shear response of masonry walls under in-plane loading can be largely dependent on the shear bond strength (failure load described by the Coulomb friction criterion) or on the in-plane tensile strength of masonry (failure load described by the Turnšek and Čačovič criterion). The bond strength of the masonry joints and the in-plane tensile strength of masonry play an important role on the flexural resistance of masonry. The tensile strength is more important than the flexural strength in the direction parallel to the bed joints and the tensile bond strength of primary importance in case of the flexural strength in the normal direction to the bed joints.

Macro-block; Macro-element

Introduction

The structural analysis involves the definition of the model and selection of the analysis type. The model should represent the stiffness, the mass, and the loads of the structure. The structures can be represented using simplified models, such as the lumped mass models, and advanced models resorting the finite element method (FEM) and discrete element method (DEM). Depending on the characteristics of the structure, different types of analysis can be used such as limit analysis, linear and nonlinear static analysis, and linear and nonlinear dynamic analysis.

Unreinforced masonry structures present low tensile strength, and the linear analyses seem to not be adequate for assessing their structural behavior. On the other hand, the static and dynamic nonlinear analyses are complex, since they involve large time computational requirements and advanced knowledge of the practitioner. The nonlinear analysis requires advanced knowledge on the material properties, analysis tools, and interpretation of results. The limit analysis with macro-blocks can be assumed as a more practical method in the estimation of maximum load capacity of structure. Furthermore, the limit analysis requires a reduced number of parameters, which is an advantage for the assessment of ancient and historical masonry structures, due to the difficulty in obtaining reliable data.

The observation of the damage in masonry buildings caused by earthquakes in the past has been shown that the masonry structures can be discretized into several macro-blocks and interfaces.

The macro-blocks are portions of a structure with similar material properties and structural behavior, to which the mechanical properties of the material can be assigned or, by simplification, they can be assumed to be infinitely rigid. The interfaces in a macro-modelling represent, in general, the cracks associated to the failure mechanisms. However, in a micro-modelling strategy applied to masonry, in which the units and the joints are individually considered, the interfaces simulate the behavior of the joints. Furthermore, different criteria for the strength parameters of macro-blocks and interfaces can be considered.

The limit analysis (Fig. 1) with macro-blocks is a simplified and powerful structural analysis

Masonry Macro-block Analysis, Fig. 1 Maximum load capacity obtained from the pushover analysis and limit analysis

tool to evaluate the ultimate capacity of masonry structures by static models, involving the equilibrium of the macro-blocks through the limit analysis basic concepts.

Classic Limit Analysis Concepts

In the classic limit analysis using rigid-plastic material behavior, a yield function τ based on stresses is defined, and three states are considered (Fig. 2): (i) if $\tau < 0$, the material presents rigid behavior and the material remains undamaged; (ii) if $\tau = 0$, the material becomes plastic and corresponds to the yield surface; (iii) if $\tau > 0$, the stress state is inadmissible. The points inside or on the yield function correspond to the states in which the stress can be sustained by the material, and the points outside correspond to stress states inadmissible for the material. The classic limit analysis considers that when the stress states are on the yield surface, the material becomes plastic and the flow direction is normal to the yield surface. This assumption is called as associated flow or normality condition. The associated flow implies that the yield surface must be convex and provides the maximum energy dissipation (Nielsen 1999).

A general load on a structure can be multiplied by a load factor δ and increased from zero to a limit (failure load factor δ_F) for which the structure remains the equilibrium condition (equilibrium between internal and external forces) and the yield condition (the stresses must be less than or equal to the material strength),

Masonry Macro-block Analysis, Fig. 2 Classic limit analysis theory

Masonry Macro-block Analysis,

Fig. 3 Graphical representation of the limit analysis theorems

i.e., the structure remains safe. This approach is associated to the static or lower bound theorem of the classic limit analysis, in which the safety factor is the largest of all the statically admissible load factors (δ_L). Furthermore, the classic limit analysis presents the kinematic approach, in which a sufficient number of releases (e.g., plastic hinges) have to occur to transform the structure into a mechanism. Each kinematically admissible mechanism presents an associated load factor, which is, in general, larger or equal to the safety factor. This approach corresponds to the kinematic or upper bound theorem of the classic limit analysis, in which the safety factor is the smallest of all kinematically admissible load factors (δ_U). The largest load factor obtained from the static theorem and the smallest load factor obtained from the kinematic theorem are the same, stating that a structure can present a statically admissible state and be unsafe if a sufficient number of sections reach the yield surface to transform the structure into a mechanism. This particular case corresponds to the uniqueness theorem of the classic limit analysis. The graphical representation of the theorems of classic

limit analysis is presented in Fig. 3 and is summarized as follows (Kamenjarzh 1996; Nielsen 1999):

- Static or lower bound theorem: If a load presents a magnitude such that the stress state satisfies the equilibrium and yield conditions, then the structure will not collapse and the load factor (δ_L) is less than or equal to failure load factor (δ_F). In this static approach the failure load factor is determined by searching for the maximum load factor.
- Kinematic or upper bound theorem: If a kinematic admissible mechanism can be found for which the work of the external loads exceeds the internal work, then the structure will collapse and the load factor (δ_U) is greater than or equal to the failure load factor (δ_F). In the kinematic approach the failure load factor is determined by searching for the minimum load factor.
- Uniqueness theorem: If the equilibrium, mechanism, and yield conditions are satisfied, then the load factor obtained from the static and kinematic approach is the same and is equal to the failure load factor (δ_F). Thus, the

failure load factor is determined by equating the load factors of both approaches and using, for example, optimization techniques.

Application of Limit Analysis in Masonry Structures

Heyman (1966) was among the first and the most famous promoters to use the limit analysis based on plasticity theory on arches and other masonry structures. Although the masonry is a quasi-brittle material, the plastic limit analysis was used to assess the structural behavior of masonry structures, assuming the following assumptions:

- Masonry has no tensile strength: Masonry presents low tensile strength and quasi-brittle tensile behavior, mainly in ancient masonry structures built with weak mortar, justifying this assumption.
- Masonry has infinite compressive strength: In general, masonry presents a compressive strength higher than the compressive stresses present in the structure. For this reason, the most cases of collapse of masonry buildings

are related to tensile and shear failures. Thus, this assumption is in general accepted and the crushing failure of masonry is not considered.

- Sliding failure is not permitted: Although the sliding between units can sometimes occur at the joints, in general the sliding failure is not the most relevant failure mechanism and this assumption can be accepted.

The failure load assessment of masonry structures based on the limit analysis and the assumptions defined by Heyman (1966) can be carried out using two approaches: (a) static approach and (b) kinematic approach.

In the static approach the resultant of the compressive stresses is plotted at each cross section of the structure. The line containing all the positions of the compressive stress resultants is called by thrust line (Fig. 4a). The thrust line can be determined by analytical methods or graphical methods, such as funicular polygon (Kooharian 1952). The structure is safe when the thrust line is located totally inside of the geometry of structure and the equilibrium with the external loads can be found. In this conditions and according to the lower bound theorem, the applied load is less

Masonry Macro-block Analysis, Fig. 4 Application of the limit analysis to a masonry arch: (a) static approach (lower bound theorem); (b) kinematic approach (upper bound theorem); (c) uniqueness theorem

than or equal to the failure load. Nevertheless, several thrust lines contained in the geometry of the structure can be found, meaning that the thrust line definition is an indeterminate problem (hyperstatic structure), where a solution can be obtained by using an iterative method. Thus, if the thrust line is found to be totally inside of the geometry of structure that was found, the structure is safe, which does not mean that the structure necessarily works according to this solution. However, nothing can be concluded with respect to the stability if the thrust line is outside of the geometry of structure, unless the infinite possibilities were tried.

With regard to kinematic approach, when the structure presents an enough number of hinges to transform it into a mechanism (Fig. 4b), the load factor obtained by equating the work of the external loads to zero corresponds to an upper bound limit (upper bound theorem). The load obtained from the kinematic approach is greater than or equal to the failure load. Different positions for the hinges on the structure can be adopted, and several mechanisms, and respective load factors, can be found. The mechanism that presents the lowest load factor corresponds to the collapse mechanism. Thus, the kinematic approach presents also several solutions.

Taking into account the results obtained from both approaches, the static approach presents a safe solution of the maximum load capacity of masonry structures. However, for complex masonry structures it can be difficult to predict the position of the thrust line. On the other hand, the kinematic approach can lead to an unsafe estimation of the ultimate load. This problem can be solved by implementing computational tools of optimization and searching by the failure load (minimum load factor).

A particular case can occur when the thrust line becomes tangent to the boundaries of the geometry at an enough number of cross sections to create a mechanism (Fig. 4c). In this condition, the mechanism corresponds to the collapse mechanism, the thrust line is unique, and the load corresponds to the failure load (uniqueness theorem).

The assumptions adopted for the limit analysis of masonry structures are simplifications of its real and complex structural behavior. In fact,

the compressive strength of masonry is not infinite, and the structures can present high concentrations of compressive stress. The use of finite compressive strength for masonry is more realistic and can provide a small reduction of the load factor at the collapse. Furthermore and as previously mentioned, the sliding failure can occur, which can be a nonconservative assumption for some particular construction techniques of masonry (e.g., sliding at the interface between the rings of a multi-ring masonry bridge). The consideration of the sliding failure implies the lack of the normality condition (nonassociated flow). Thus, several researchers have been conducting efforts to develop limit analysis considering the crushing, the sliding, and the twisting failures of masonry. For more information on innovate limit analyses of masonry structures, see, e.g., Orduña and Lourenço (2003), Gilbert et al. (2006), and Portioli et al. (2013).

Macro-block Approach

The limit analysis with macro-blocks allows to determine the maximum load capacity of structures by using simple procedures based on kinematic approach and involving the equilibrium of the macro-blocks. A macro-block corresponds to a portion of structures with similar material properties and structural behavior, which can represent the structural element (e.g., piers) or a set of structural elements (e.g., a façade). In this approach, the structure is discretized in several macro-blocks with independent structural behaviors. This type of analysis is a practical tool for assessing of the structural behavior of structures and does not require a high number of parameters for the material properties.

The existing masonry structures present in general local modes under an earthquake, due to the loss of equilibrium of parts of the structure. Thus, the limit analysis using macro-blocks is particularly suitable for evaluating the seismic performance of existing masonry buildings, considering even the in-plane or the out-of plane collapse mechanisms (Fig. 5). It should be noted that the out-of-plane behavior of masonry

Masonry Macro-block Analysis, Fig. 5 Examples of collapse mechanisms using macro-blocks: (a) in-plane collapse of façade; (b) out-of-plane collapse of façade

structures is complex and that in general this typology of buildings does not satisfy the assumptions of the typical static nonlinear analysis imposing lateral forces proposed for reinforced concrete buildings (rigid floors, regularity in plan and in elevation, and response governed by the first mode). Furthermore, this type of analysis is also a useful tool for evaluating the efficiency of strengthening techniques applied to existing masonry buildings.

In general, the application of limit analysis with rigid macro-blocks for masonry structures is based on the assumptions proposed by Heyman (1966) (no tension strength, infinite compressive strength, and the sliding cannot occur). However, more realist assumptions can be considered, such as a finite compressive strength.

The macro-block approach involves a first step for selection of mechanisms. The mechanisms can be proposed on the basis of the knowledge obtained from the post-earthquake survey of similar buildings, using the crack patterns obtained from the experimental research, and on the basis of the practitioner experience. The selection of the mechanisms to consider is a fundamental step in this type of analysis and requires a detailed knowledge of the features of the structure, such as the quality of the connections between masonry and the connections between masonry walls and floors, the presence

of cracks, and the interaction with adjacent buildings. In fact, a bad evaluation of the possible mechanisms can lead to the non-consideration of the mechanism with the lowest load factor and, consequently, can lead to a failure load higher than the real maximum capacity of the structure. However, the main local collapse mechanisms of masonry building typologies have been compiled in abacus on the form of graphical interpretations schemes, such as the abacus for religious and urban masonry buildings (D'Ayala and Speranza 2002; Lagomarsino and Podesta 2004). Next, the load factor of each considered mechanism is determined by applying the principle of virtual works, and the mechanism that presents the lowest load factor is assumed as the collapse mechanism. Finally, the stability of the structure is analyzed, taking into account the load factor of the collapse mechanism and the requirements defined in the codes (e.g., by comparing the maximum capacity in terms of horizontal acceleration on the structural and the demands in terms of peak ground acceleration (PGA)).

Subsequently, an example of application of the limit analysis with rigid macro-blocks for masonry structures is presented.

Example of Application

Figure 6a presents a possible out-of-plane mechanism of a façade from masonry buildings with

Masonry Macro-block Analysis, Fig. 6 Out-of-plane collapse of tied masonry wall: (a) general view; (b) scheme of the mechanism

ties at the top and subjected to a seismic action with uniform acceleration acting in the orthogonal direction to the plan of the façade. The structure presents three horizontal cracks at the façade and two cracks at the corners. This local mechanism is composed by three hinges, in which the hinge associated to the crack within the wall is not initially known. Figure 6b shows the scheme of the mechanism in analysis. The height H and thickness T of the masonry wall are equal to 3.50 m and 0.30 m, respectively. The specific mass of the masonry γ is equal to 20 kN/m³. Furthermore, it is assumed that the vertical force at the top of the masonry wall N is equal to 10 kN/m.

The first step corresponds to the determination of the variables of rotation (θ) and displacements of the macro-blocks at the center of mass (u) in the vertical and horizontal directions. Since the position of the crack within the wall is not known, the heights of the macro-blocks are defined as a function of the variable X :

$$h_1 = XH = 3.5H \quad (1)$$

$$h_2 = (1 - X)H = (1 - 3.5)H \quad (2)$$

If a rotation $\theta_1 = 1$ is given to macro-block 1, then the macro-block 2 rotation is:

$$\begin{aligned} \theta_1 h_1 &= \theta_2 h_2 \\ \theta_2 &= \frac{h_1}{h_2} \theta_1 \\ \theta_2 &= \left(\frac{X}{1 - X} \right) \theta_1 = \frac{X}{1 - X} \end{aligned} \quad (3)$$

and the displacements of the macro-blocks and of application of the vertical force N are:

$$u_{1,x} = \frac{h_1}{2} \theta_1 = \frac{XH}{2} = \frac{3.5}{2} X \quad (4)$$

$$\begin{aligned} u_{1,y} &= \frac{T}{2} \theta_1 + T \theta_2 = \frac{T}{2} + T \frac{X}{1 - X} \\ &= 0.15 + 0.30 \frac{X}{1 - X} \end{aligned} \quad (5)$$

$$u_{2,x} = \frac{h_2}{2} \theta_2 = \frac{(1-X)}{2} H \frac{X}{(1-X)} = \frac{XH}{2} = \frac{3.5}{2} X \quad (6)$$

$$u_{2,y} = \frac{T}{2} \theta_2 = \frac{T}{2} \frac{X}{(1-X)} = 0.15 \frac{X}{(1-X)} \quad (7)$$

$$u_{B,y} = u_{1,y} = \frac{T}{2} = 0.15 + 0.30 \frac{X}{1-X} \quad (8)$$

The forces applied at the macro-blocks due to the self-weight (P) and the inertial forces proportional to mass (F) are:

$$P = \gamma TH = 21 \text{ kN/m} \quad (9)$$

$$P_1 = PX = 21X \quad (10)$$

$$P_2 = P(1-X) = 21(1-X) \quad (11)$$

$$F = \delta P = 21\delta \quad (12)$$

$$F_1 = \delta P_1 = 21X\delta \quad (13)$$

$$F_2 = \delta P_2 = 21(1-X)\delta \quad (14)$$

where δ is the load factor. P and F are forces by meter of wall width.

The application of the principal of virtual works provides:

$$\begin{aligned} & -P_1 u_{1,y} - P_2 u_{2,y} - N u_{B,y} + F_1 u_{1,x} + F_2 u_{2,x} = 0 \\ & - \left(3.15X + \frac{6.3X^2}{1-X} \right) - (3.15X) - \left(1.5 + \frac{3X}{1-X} \right) \\ & + (36.75X^2\delta) + (36.75X\delta - 36.75X^2\delta) \\ & = 0 - 6.3X - \frac{(3X + 6.3X^2)}{1-X} - 1.5 + 36.75X\delta = 0 \end{aligned} \quad (15)$$

Thus, it is possible to obtain the load factor as a function of X :

$$\delta = \frac{6.3X + \frac{(3X + 6.3X^2)}{1-X} + 1.5}{36.75X} \quad (16)$$

The minimum load factor δ can be computed by equating the:

$$\frac{d\delta}{dx} = 0 \quad (17)$$

and a value of X equal to 0.287 is obtained. Replacing the value of X in the Eq. 16, the minimum load factor is equal to 0.50, leading to the conclusion that position of the crack within of façade that cause the minimum load factor is equal to 2.50 m with respect to the base of structure ($h_2 = 2.50$ m).

Summary

The limit analysis with macro-blocks is a simple tool for evaluating the maximum load capacity of masonry structures. The possible mechanisms are proposed and then the respective load factors are determined. The mechanism that presents the minimum load factor corresponds to the collapse, and its load factor is assumed as the failure load. Thus, a careful evaluation of the possible mechanisms is needed, aiming at not excluding any important mechanism and predicting correctly the maximum load capacity of the structure.

The macro-block analysis applied to masonry structures is based on the first assumptions used for the classic limit analysis of arches (no tension strength, infinite compressive strength, the sliding cannot occur), which is acceptable for the majority of the masonry buildings. However, several approaches considering more realistic assumptions have been proposed and implemented in computational tools, aiming at improving the capabilities and the applicability of this type of analysis.

As final conclusion, the limit analysis with macro-blocks is a powerful tool for the seismic assessment of masonry structures, including the historical buildings and the out-of-plane behavior. Furthermore, it allows evaluating the efficiency of strengthening techniques.

Introduction

This entry deals with modeling of masonry structures. In general, the approach towards the numerical representation of masonry can focus on the micro-modeling of the individual

components, units and mortar, or the macro-modeling of masonry as a composite (Rots 1991). Much effort is made today in the link between the micro- and macro-modeling approaches using homogenization techniques.

Masonry joints act as planes of weakness, and the explicit representation of the joints and units in a numerical model seems a logical step towards a rigorous analysis tool (Fig. 1). This kind of analysis is particularly adequate for small structures, subjected to states of stress and strain strongly heterogeneous, and demands the knowledge of each of the constituents of masonry (unit and mortar) as well as the interface. In terms of modeling, all the nonlinear behavior can be concentrated in the joints and in straight potential vertical cracks in the centerline of all units. In general, a higher computational effort ensues, so this approach still has a wider application in research and in small models for localized analysis.

The approach based on the use of averaged constitutive equations seems to be the only one suitable to be employed a large-scale finite element analyses. Two different approaches are illustrated in Fig. 2, one collating experimental data at average level and another from homogenization techniques. A major difference is that homogenization techniques provide continuum average results as a mathematical process that includes the information on the microstructure.

These three different approaches, namely, micro-modeling, macro-modeling, and homogenization, are reviewed next.

Micro-Modeling

Different approaches are possible to represent heterogeneous media, namely, the discrete element method, the discontinuous finite element method (FEM), and limit analysis. The finite element method remains the most used tool for numerical analysis in solid mechanics, and an extension from standard continuum finite elements to represent discrete joints was developed in the early days of nonlinear mechanics.

Masonry Modeling, Fig. 1 Examples of cracking at failure using structural micro-modeling: (a) shear wall with opening; (b) wall subjected to out-of-plane loading; (c) retaining wall

Interface elements were initially employed in concrete and rock mechanics, being used since then in a great variety of structural problems. A complete micro-model must include all the failure mechanisms of masonry, namely, cracking of joints, sliding over one head or bed joint, cracking of the units, and crushing of masonry, as done in (Lourenço and Rots 1997) for monotonic loading and in (Oliveira and Lourenço 2004) for cyclic loading.

The typical characteristics of discrete element methods are (a) consideration of rigid or FEM deformable blocks, (b) connection between vertices and sides/faces, (c) interpenetration usually possible, and (d) explicit integration of the equations of motion for the blocks using the real damping coefficient (dynamics) or artificially large (statics). The main advantages are the formulation for large displacements, including contact update, and an independent mesh for each block, in case of deformable blocks. The main disadvantages are the large number of contact points required for accurate representation of interface stresses and a time-consuming analysis, especially for 3D problems. Masonry applications can be found in (Lemos 2007).

Computational limit analysis received far less attention from the technical and scientific community for blocky structures. Still, limit analysis has the advantage of being a simple tool, while having the disadvantages that only collapse load and collapse mechanism can be obtained and loading history can hardly be included. A limit analysis constitutive model for masonry that incorporates nonassociated flow at the joints, tensile, shear, and compressive failure and a novel formulation for torsion is given (Orduña and Lourenço 2005a, b). The salient characteristics of limit analysis are (a) rigid blocks, (b) interpenetration not allowed, and (c) mathematical formulation that leads to an optimization problem (linear or nonlinear). The main advantages of the technique are adequate formulation for design problems (requires a low number of parameters) and fast analysis. The main advantages are that only the collapse load and mechanism can be obtained, tensile strength cannot be included in the analysis, and the introduction of the loading history remains a challenge.

As an example of the possibilities that can be achieved with micro-modeling, a powerful

Masonry Modeling, Fig. 2 Constitutive behavior of materials with microstructure: (a) collating experimental data; (b) mathematical process using geometry and mechanics of components

Masonry Modeling, Fig. 3 Multi-surface interface constitutive model

interface model is applied to illustrative examples. A constitutive interface model can be defined by a convex composite yield criterion (see Fig. 3), composed by three individual yield functions, usually with softening included for all

modes so that experimental observations can be replicated. The three functions include the usual Coulomb friction criterion for shear, combined with tension and compression cutoffs. The adoption of appropriate inelastic constitutive relations

Masonry Modeling, Fig. 4 Comparison between experimental and numerical results for uniaxial testing: (a) tension; (b) compression; (c) shear; (d) tension-compression

and evolution rules makes possible to reproduce nonlinear behavior during loading, unloading, and reloading, consisting of exponential softening for tension and shear, and parabolic hardening followed by exponential softening in compression (see Fig. 4). In this case, isotropic and kinematic hardening laws are used, and aspects related to the algorithm can be found in (Oliveira and Lourenço 2004).

The ability of the model to reproduce the main features of structural masonry elements is shown in Fig. 5. Shear walls have been used traditionally to validate constitutive models and to characterize masonry structural solutions, due to the fact that the most demanding demand for a masonry building with box behavior usually leads to a combination of vertical and horizontal loading.

For the first wall considered, it was found that the geometric asymmetry in the microstructure (arrangement of the units) influenced significantly its structural behavior. Note that, depending in the loading direction, the masonry course starts either with a full unit or only with half unit. Figure 5a shows that the monotonic collapse load is 112.0 kN in the LR direction and 90.8 kN in the RL direction, where L indicates left and R indicates right. The cyclic collapse load is 78.7 kN, which represents a loss of about 13 % with respect to the minimum monotonic value but a loss of about 30 % with respect to the maximum monotonic value. This demonstrates the importance of cyclic loading but also the importance of taking into account the microstructure. It is also clear from these analyses that masonry shear walls with diagonal zigzag cracks

Masonry Modeling, Fig. 5 Results obtained with interface cyclic loading model for shear walls, in terms of force–displacement diagram and failure mode: **(a)** wall failing in shear; **(b)** wall failing in bending

possess an appropriate seismic behavior with respect to energy dissipation.

The second wall considered (Fig. 5b) is a tall wall that simply rocks in both ways. The highly nonlinear shape of the load–displacement curve is essentially due to the opening and subsequent closing, under load reversal, of the top and bottom bed joints. Similar deformed patterns, involving the opening of extreme bed joints, were observed during the experimental test. Numerical results show that the cyclic behavior of the wall is controlled by the opening and closing of the top and bottom bed joints, where damage is mainly concentrated. The model also

shows low (static) energy dissipation, which is a consequence of the activated nonlinear mechanism (opening–closing of joints and the absence of a diagonal shear crack). As shown, the failure of this wall is much different from the previous wall, stressing the relevance of the internal structure.

Macro-Modeling

Difficulties of conceiving and implementing macro-models for the analysis of masonry structures arise especially due to the fact that few

Masonry Modeling,**Fig. 6** Continuum failure surface for masonry (plane stress representation)**Masonry Modeling, Fig. 7** Behavior of the model for (a) tension and (b) compression, along two orthogonal directions

experimental results are available (either for pre- and post-peak behavior), but also due to the intrinsic complexity of formulating anisotropic inelastic behavior. Only a reduced number of authors tried to develop specific models for the analysis of masonry structures (Dhanasekar et al. 1985; Seim 1994; Lourenço et al. 1998; Berto et al. 2002; Pelà et al. 2011), always using the finite element method.

Formulations of isotropic quasi-brittle materials behavior consider, generally, different inelastic criteria for tension and compression. The new model introduced in (Lourenço et al. 1997), extended to accommodate shell masonry behavior (Lourenço 2000), combines the advantages of modern plasticity concepts with a powerful representation of anisotropic material behavior, which includes different

hardening/softening behaviors along each material axis. The model includes the combination of a Rankine-like yield surface for tension and a Hill-like yield surface in compression (see Fig. 6). The behavior of the model in uniaxial tension and uniaxial compression, along two orthogonal directions, is given in Fig. 7. This composite surface permits to reproduce the results obtained in uniaxial tests, in which different behaviors are obtained along different directions. The application of the model in structural modeling of masonry structures leads to excellent results, both in terms of collapse loads and in terms of reproduced behavior (see Lourenço et al. 1998; Lourenço 2000).

Figure 8 shows the results of modeling another shear wall with an initial vertical pre-compression pressure. The horizontal force

Masonry Modeling, Fig. 8 Results for masonry shear wall: (a) load-displacement diagram; (b) predicted cracking pattern at peak and ultimate load

Masonry Modeling, Fig. 9 Results for a panel subjected to uniform out-of-plane loading: predicted cracking pattern at (a) bottom and (b) top face of the panel

F drives the wall to failure and produces a horizontal displacement d at top. The wall is confined by two concrete slabs (top and bottom) and two masonry flanges (left and right). This confinement and the large size of the wall make it appropriate for continuum modeling. Initially, cracking occurs well distributed in the panel and finally concentrates in a single shear band from one corner of the panel to the other. The compressive stresses are well below the crushing strength of masonry, i.e., failure is dominated by tension. A complete discussion of the numerical

results has been given in (Lourenço et al. 1998). Figure 9 shows the results of modeling a panel with out-of-plane pressure. The panel is simply supported on two sides (left and right), fully clamped on one side (bottom), and free on the other (top). The central opening simulates a window, and the panel was loaded with an air bag with a uniformly distributed load. The predicted form of collapse includes diagonal cracks from each lower corner of the panel up to the opening, which were also observed in the experiments. This form of yield line collapse

does not mean that yield line design is safe due to the quasi-brittle behavior of the material. A complete discussion of the numerical results has been given in Lourenço (2000). A discussion on the application of these models to large historic constructions is given in Lourenço (2002).

Homogenization Approaches

Homogenization techniques permit the establishment of constitutive relations in terms of average stresses and strains from the geometry and constitutive relations of the individual components. This can represent a step forward in masonry modeling because of the possibility to use standard isotropic material models and data for masonry components, instead of the rather expensive approach of testing large masonry specimens under homogeneous loading conditions.

The complex geometry of the masonry representative volume, i.e., the geometrical pattern that repeats periodically in space, means that no closed-form solution of the problems exists for running bond masonry. One of the first ideas presented was to substitute the complex geometry of the basic cell with a simplified geometry, so that a closed-form solution for the homogenization problem was possible. This approach, rooted in geotechnical engineering applications, assumed masonry as a layered material (Lourenço 1996). This simplification does not allow including information on the arrangement of the masonry units and provides significant errors in the case of nonlinear analysis. Moreover, the results depend on the sequence of homogenization steps. To overcome the limitation, micro-mechanical homogenization approaches that consider additional internal deformation mechanisms have been derived (Zucchini and Lourenço 2002, 2009). The implementation of these approaches in standard macroscopic finite element nonlinear codes is relatively simple, and the approaches can compete with macroscopic approaches (see Lourenço et al. (2007) for a detailed review on homogenization approaches).

A powerful micro-mechanical model for the limit analysis for masonry has been recently developed (Milani et al. 2006a, b). In this model, the elementary cell is subdivided along its thickness in several layers. For each layer, fully equilibrated stress fields are assumed, adopting polynomial expressions for the stress tensor components in a finite number of sub-domains. The continuity of the stress vector on the interfaces between adjacent sub-domains and suitable anti-periodicity conditions on the boundary surface are further imposed. In this way, linearized homogenized surfaces in six dimensions for masonry in- and out-of-plane loaded are obtained. Such surfaces are then implemented in a finite element limit analysis code for simulation of 3D structures and including, as recent advances, blast analysis, quasiperiodic masonry internal structure, and FRP strengthening. Figure 10 shows a masonry wall constituted by a periodic arrangement of bricks and mortar arranged in running bond. For a general rigid-plastic heterogeneous material, homogenization techniques combined with limit analysis can be applied for the evaluation of the homogenized in- and out-of-plane strength domain.

The homogenized failure surface obtained has been coupled with finite element limit analysis. Both upper- and lower-bound approaches have been developed, with the aim to provide a complete set of numerical data for the design and/or the structural assessment of complex structures. The finite element lower-bound analysis is based on an equilibrated triangular element, while the upper bound is based on a triangular element with discontinuities of the velocity field in the interfaces. Recent developments include the extension of the model to blast analysis (Milani et al. 2009), to quasiperiodic masonry (Milani et al. 2010), and to FRP strengthening (Milani and Lourenço 2013).

An enclosure running bond masonry wall subjected to a distributed blast pressure is considered first (Milani et al. 2010). The wall is supposed simply supported at the base and on vertical edges and free on top due to the typical imperfect connection between infill wall and RC

Masonry Modeling, Fig. 11 Masonry infill wall subjected to blast pressure: comparison among deformed shapes at $t = 400 \mu\text{s}$ for (a) homogenized limit analysis

and heterogeneous 3D elastic-plastic FE approach; (b) comparison between maximum out of plane displacements and limit analysis failure mode

beam. A full 3D FE heterogeneous elastic-plastic dynamic analysis has been also conducted, in order to have a deep insight into the problem and to collect alternative data to compare with. For the 3D model, a rigid infinitely resistant behavior for bricks was assumed, whereas for joints, a Mohr-Coulomb failure criterion with the same tensile strength and friction angle used in the homogenized approach for joints was adopted. Eight-noded brick elements were utilized both for joints and bricks, with a double row of elements along wall thickness. A comparison between the deformed shapes at $t = 400 \mu\text{s}$ obtained with the present model and the commercial software is schematically depicted in Fig. 11a. As it is possible to notice, the models give almost the same response in terms of deformed shape for the particular instant

time inspected, confirming that reliable results may be obtained with the model proposed. On the other hand, it is worth underlining that the homogenized rigid-plastic model required only 101 s to be performed on a standard PC Intel Celeron 1.40 GHz equipped with 1Gb RAM, a processing time around 10–3 lower than the 3D case. Comparisons of time-maximum displacement diagrams provided by the two models analyzed are reported in Fig. 11b, together with the evolution of the deformation provided by the homogenized model proposed.

Recently, two different classes of problems have been investigated (Milani et al. 2010), the first consisting of full stochastic representative element of volume (REV) assemblages without horizontal and vertical alignment of joints and the second assuming the presence of a horizontal

Masonry Modeling, Fig. 12 Church of Gondar (Portugal), FE discretization adopted: (a) heterogeneous random mesh vs. mesh for running bond regular heterogeneous and homogenized random analysis; (b) ECDF of

the failure load provide through a direct heterogeneous approach and homogenized limit analysis simulations

alignment along bed joints, i.e., allowing block height variability only row by row. The model is characterized by a few material parameters, and it is therefore particularly suited to perform large-scale Monte Carlo simulations. Masonry strength domains are obtained equating the power dissipated in the heterogeneous model with the power dissipated by a fictitious homogeneous

macroscopic plate. A stochastic estimation of out-of-plane masonry strength domains (both bending moments and torsion are considered) accounting for the geometrical statistical variability of blocks dimensions is obtained with the proposed model. The case of deterministic block height (quasiperiodic texture) can be obtained as a subclass of this latter case. As an important

benchmark, the case in which joints obey a Mohr–Coulomb failure criterion is also tested and compared with results obtained assuming a more complex interfacial behavior for mortar. In order to show the capabilities of the approach proposed when dealing with large-scale structures, the ultimate behavior prediction of a Romanesque masonry church facade located in Portugal are presented. Comparisons with finite element heterogeneous approaches and “at hand” calculations show that reliable predictions of the load bearing capacity of real large-scale structures may be obtained with a very limited computational effort (see Fig. 12).

Conclusions

Constraints to be considered in the use of advanced modeling are the cost, the need of an experienced user/engineer, the level of accuracy required, the availability of input data, the need for validation, and the use of the results. As a rule, advanced modeling is a necessary means for understanding the behavior and damage of masonry constructions. For the study of isolated structural elements and problems controlled by the geometry of a few units, micro-modeling strategies are available. For large-scale applications, average continuum mechanics is usually adopted, and homogenization techniques represent a popular and active field in masonry research. The assessment and design of unreinforced masonry structures subjected to seismic loading is particularly challenging when masonry box behavior is not present. In this case, macro-block analysis seems adequate for simplified assessment and design of strengthening measures.

Summary

Masonry joints act as planes of weakness, and the explicit representation of the joints and units in a numerical model seems a logical step towards a rigorous analysis tool (Fig. 1). This kind of

analysis is particularly adequate for small structures, subjected to states of stress and strain strongly heterogeneous. In general, a higher computational effort ensues, so this approach still has a wider application in research and in small models for localized analysis. The approach based on the use of averaged constitutive equations seems to be the most suitable to be employed a large-scale finite element analyses, either by collating experimental data at average level (macro-modeling) or from homogenization techniques.

A micro-model for masonry joints is usually composed by three individual yield functions, consisting of the usual Coulomb friction criterion for shear, combined with tension and compression cutoffs. A macro-model for the masonry composite must permit to reproduce the results obtained in uniaxial tests, with distinct behavior obtained along different directions. Finally, homogenization techniques require as input the geometry of the units and joints, as well as their mechanical properties. The most successful applications are based on micromechanical models that perform a simplified single-step homogenization because a close form solution is not available.

This entry provides a review of different modeling approaches for masonry structures with illustrative applications.

Brick; Building; Concrete; Housing; Mortar; Stone; Structural analysis

Introduction

Masonry is the oldest building material that still finds wide use in today's building industries. The most important characteristic of masonry construction is its simplicity. Laying pieces of stone, bricks, or blocks on top of each other, either with or without cohesion via mortar, is a simple, though adequate, technique that has been successfully used ever since remote ages. Naturally, innumerable variations of masonry materials, techniques, and applications occurred during the course of time. The influence factors were mainly the local culture and wealth, the knowledge of materials and tools, the availability of material, and architectural reasons.

The primitive savage endeavors of mankind to secure protection against the elements and from attack included seeking shelter in rock caves, learning how to build tents of bark, skins, turfs, or brushwood and huts of wattle and daub. Some of such types crystallized into houses of stone, clay, or timber. The evolution of mankind is thus linked to the history of building materials.

The first masonry material to be used was probably stone. In the ancient Near East, evolution of housing was from huts, to apsidal houses (Fig. 1a), and finally to rectangular houses (Fig. 1b). The earliest examples of the first permanent houses can be found near Lake Hullen, Israel (c. 9000–8000 BC), where dry-stone huts, circular and semisubterranean, were found. Several other legacies survived until present

Masonry Structures: Overview, Fig. 1 Examples of prehistoric architecture of masonry in the ancient Near East: (a) beehive houses from a village in Cyprus (c. 5650 BC); (b) rectangular dwellings from a village in Iraq

as testimonies of ancient and medieval cultures (Fletcher and Cruikshank 1996), often as a stone skeleton (Heyman 1997).

The first assault to the use of structural masonry happened at the middle of the nineteenth century, when cast-iron beams and columns started to be produced. By the end of the century, skyscraper constructions methods had eliminated the necessity of massive ground-level piers of masonry. Nevertheless, the collapse of masonry as a structural material started in the beginning of the twentieth century, with the introduction of German, French, and British regulations for design of reinforced concrete structures. Concrete was used in constructions of walls as early as the fourth-century BC around Rome. But, only in 1854, a system for reinforced concrete was patented in Britain by W.B. Wilkinson. By the beginning of the twentieth century, it was clear that reinforced concrete was a durable, strong, moldable, and inexpensive material, and masonry was practically forgotten as a structural material in several developed countries.

In Europe, the building solutions using unreinforced structural masonry represent about 15 % to more than 50 % of the new housing construction, taking as reference countries with low seismicity (e.g., Germany, Netherlands, or

Norway) but also countries with high seismicity (e.g., Italy). A usual solution is the adoption of masonry units with large thickness in the building envelope to fulfill thermal requirements. It is stressed that an integrated and complete building technology is needed, including units with different shapes and solutions for floors. Reinforced masonry was developed in different countries as a response to the lower performance of unreinforced masonry buildings under large horizontal loading, but no unified solution was found. Diverse solutions with different levels of success coexist, together with recent innovative solutions.

It is common practice to combine prefabricated slabs with load-resisting walls so that formwork, scaffolding, and execution times can be significantly reduced. In the USA, in the last 30–40 years, reinforced masonry became an attractive and efficient solution from a perspective of cost-benefit analysis for buildings in regions of low to high seismicity, e.g., hotels, residential buildings, office buildings, schools, commercial buildings, or warehouses. The American standard solution includes reinforced concrete horizontal bond beams, two-cell blocks filled with grout, and vertical reinforcement. Besides other reinforced masonry

approaches, confined masonry is popular in developing countries, as the changes with respect to unreinforced masonry construction are small. In this system vertical and horizontal reinforced concrete elements of small section are included in the masonry. These elements aim at providing an increase of shear and flexural strength, together with a larger energy dissipation capacity and larger ductility with respect to horizontal actions.

The last decades have witnessed an enormous development in the characterization of masonry materials and in numerical methods for structural analysis. Today, with the help of a computer, it is possible to analyze structures with a high level of accuracy. The material science (directly dependent on the observation and analysis of the experimental behavior) has suffered a slower evolution, but important advances in constitutive models and structural component models have occurred in various fields. For a long time, it was believed that the decline of masonry as a structural material was not only due to economic reasons but also to underdeveloped masonry codes and lack of insight in the behavior of this type of structures. This is not presently the case, as modern codes are available, e.g., Eurocode 6 or EN 1996-1-1:2005 (CEN 2005), but also modern engineering books, e.g., Drysdale and Hamid (2008), Hendry (1998), Pfefferman (1999), or Sahlin (1971), which provide general overviews of design. More specific books, with a focus on earthquake performance are also available, e.g., Tassios (1988) or Tomaževič (1999). It is stressed that the design of unreinforced masonry structures under seismic loading has not yet received general consensus.

Description

Masonry is a heterogeneous material that consists of units and joints. Units are such as bricks, blocks, ashlar, adobe, irregular stones, and others. Mortar can be clay, bitumen, chalk, lime/cement-based mortar, glue, or others. A (very) simple classification of stone masonry

is shown in Fig. 2. The huge number of possible combinations generated by the geometry, nature, and arrangement of units as well as the characteristics of mortars raises doubts about the accuracy of the term “masonry.” Just for brick masonry, some usual combinations are shown in Fig. 3.

When the walls of ancient constructions were of small width, stone units could be of the full width (bond stone or through stone). If the walls were very thick, ashlar would only be used for the outer leafs and the inside would be filled with irregular stones or rubble, or more than one leaf of masonry would be used. Indeed, physical evidence shows us that ancient masonry is a very complex material with three-dimensional internal arrangement, usually unreinforced, but which can include some form of traditional reinforcement, see Fig. 4. Moreover, these materials are associated with complex structural systems, where the separation between architectural features and structural elements is not always clear.

Modern masonry can also exhibit significant variations, not only of materials but also of building technology, see Fig. 5. The choice of materials and the thermal solution, particularly for the enclosure walls, which is a matter of growing concern, is mostly due to tradition and local availability of the materials. Also, the use of reinforcement is associated with tradition and local technological developments, with different approaches from one country to the other.

Nevertheless, the mechanical behavior of the different types of masonry has generally a common feature: a very low tensile strength. This property is so important that it has determined the shape of ancient constructions. The difficulties in performing advanced testing of ancient structures are quite large due to the innumerable variations of masonry, the variability of the masonry itself in a specific structure, and the impossibility of reproducing it all in a specimen. Therefore, most of the advanced experimental research carried out in the last decade has concentrated in brick/block masonry and its relevance for design. The masonry components are detailed in another essay.

Masonry Structures: Overview, Fig. 2 Different kinds of stone masonry: (a) rubble masonry; (b) ashlar masonry; (c) coursed ashlar masonry

Mechanics

The fact that ancient and modern masonry have so much variability in materials and technology make the task of structural analysis of these structures particularly complex. From a very simplified perspective, it is possible to distinguish masonry as reinforced and unreinforced. The presence of (distributed) reinforcement provides masonry with tensile strength and renders masonry closer to reinforced concrete. In such a case, the orthotropic behavior of masonry and the nonlinear constitutive behavior become less relevant, and the techniques normally used for the design and analysis of reinforced concrete structures can possibly be used. Conversely, in the case of unreinforced masonry structures, the very low tensile strength of the material renders the use of nonlinear constitutive behavior more obvious. This is particularly true in the assessment of existing structures and in seismic analysis.

Masonry is usually described as a material that exhibits distinct directional properties due to the

mortar joints, which act as planes of weakness. This description is associated mostly with the material, whereas a different description can be given at structural level.

Description at material level: In general, the approach toward the numerical representation of masonry, i.e., masonry modeling, can address the micro-modeling of the individual components, viz., unit (brick, block, etc.) and mortar, or the macro-modeling of masonry as a composite (CUR 1997). Depending on the level of accuracy and the simplicity desired, it is possible to use the following modeling strategies (see Fig. 6):

1. Detailed micro-modeling – units and mortar in the joints are represented by continuum elements, whereas the unit-mortar interface is represented by discontinuum elements.
2. Simplified micro-modeling – expanded units are represented by continuum elements, whereas the behavior of the mortar joints and unit-mortar interface is lumped in discontinuum elements.

Masonry Structures: Overview, Fig. 3 Different arrangements for brick masonry: (a) English (or cross) bond; (b) Flemish bond; (c) stretcher bond

M

3. Macro-modeling – units, mortar, and unit-mortar interface are smeared out in a homogeneous continuum.

In fact, the term “micro-modeling” is probably not the most adequate and the term “meso-modeling” would be more reasonable, leaving the former designation for approaches at a lower scale. But the terms macro- and micro-modeling are now widely accepted by the masonry community. A major step in the computational representation using modern analysis techniques is provided in Lourenço (1996).

Description at structural level: The simplest approach related to the modeling of masonry buildings is given by the application of different structural elements resorting to, e.g., truss, beam, panel, plate, or shell elements to represent columns, piers, arches, and vaults, with the assumption of homogeneous (macro) material behavior. Fig. 7 illustrates various possibilities.

The lumped approach or mass-spring-dashpot model of Fig. 7a is at best a crude approximation of the actual geometry of the structure, using floor levels and lumped parameters as structural components. The simplicity of the geometric model allows increased complexity on the loading side and in the nonlinear dynamic response. The structural component model in Fig. 7b approximates the actual structural geometry more accurately by using beams and joints as structural components. This approach allows the assessment of the system behavior in more detail. In particular, it is possible to determine the sequential formation of local, predefined failure mechanisms and overall collapse, both statically and dynamically. Finally, the structural model in Fig. 7c approximates the actual structural geometry using macro-blocks with a discrete set of failure lines. Most of these efforts address seismic design and assessment. Models such as the ones shown in Fig. 7a, b are adequate in case that masonry box

Masonry Structures: Overview,

behavior is exhibited by the building, whereas in Fig. 7c, the so-called macro-block analysis is adequate in case that the masonry building does not exhibit box behavior.

Accurate modeling of masonry structures requires a thorough experimental description of the material. Obtaining experimental data, which is reliable and useful for numerical models, has been hindered by the lack of communication between analysts and experimentalists. The use of different testing methods, test parameters, and materials preclude comparisons and conclusions between most experimental results. It is also current practice to report and measure only strength values and to disregard deformation characteristics. Only recently, information in the post-peak or softening regime became more widely available.

Masonry Behavior

Softening is a gradual decrease of mechanical resistance under a continuous increase of

deformation forced upon a material specimen or structure. It is a salient feature of quasi-brittle materials like clay brick, mortar, ceramics, rock, or concrete, which fail due to a process of progressive internal crack growth. Such mechanical behavior is commonly attributed to the heterogeneity of the material, due to the presence of different phases and material defects, like flaws and voids. Even prior to loading, mortar contains micro-cracks due to the shrinkage during curing and the presence of the aggregate. The clay brick contains inclusions and micro-cracks due to the shrinkage during the burning process. Stone also, usually, contains inclusions and micro-cracks. The initial stresses and cracks as well as variations of internal stiffness and strength cause progressive crack growth when the material is subjected to progressive deformation. Initially, the micro-cracks are stable which means that they grow only when the load is increased. Around peak load an acceleration of crack formation takes place and the formation of macro-cracks starts. The macro-cracks are unstable,

Masonry Structures: Overview, Fig. 5 Examples of modern masonry: (a) confined masonry in areas of moderate to high seismicity, with thick blocks; (b, c) different reinforced masonry solutions, adopted in Switzerland (left) and the USA (right)

M

Masonry Structures: Overview, Fig. 6 Modeling strategies for masonry structures: (a) detailed micro-modeling; (b) simplified micro-modeling; (c) macro-modeling

which means that the load has to decrease to avoid an uncontrolled growth. In a deformation-controlled test, the macro-crack growth results in softening and localization of cracking in a small zone while the rest of the specimen unloads.

The properties of masonry are strongly dependent upon the properties of its constituents.

Compressive strength tests are easy to perform and give a good indication of the general quality of the materials used. It is difficult to relate the tensile strength to the compressive strength due to the different shapes, materials, manufacture processes, and volume of perforations in the units. The bond between the unit and mortar is often the weakest link in masonry assemblages.

Masonry Structures: Overview, Fig. 7 Examples of structural component models: (a) lumped parameters for a complete building with 3 degrees of freedom per story;

(b) beam elements for wall with openings; (c) macro-elements for seismic assessment

The nonlinear response of the joints, which is then controlled by the unit-mortar interface, is one of the most relevant features of masonry behavior. Two different phenomena occur in the unit-mortar interface, one associated with tensile failure (mode I) and the other associated with shear failure (mode II).

Different test setups have been used for the characterization of the tensile behavior of the unit-mortar interface. These include (three-point, four-point, bond-wrench) flexural testing, diametral compression (splitting test), and direct tension testing. An important aspect in the determination of the shear response of masonry joints is the ability of the test setup to generate a uniform state of stress in the joints. This objective is difficult because the equilibrium constraints introduce nonuniform normal stresses in the joint.

Finally, the uniaxial behavior of the composite material is anisotropic, i.e., depending on the loading direction with respect to the material axes, namely, the directions parallel and normal to the bed joints. The compressive strength of masonry in the direction normal to the bed joints has been traditionally regarded as the sole relevant structural material property, at least until the recent introduction of numerical methods for masonry structures. A test frequently used to obtain this uniaxial compressive strength is the

stacked bond prism, but it is still somewhat unclear what the consequences are of using this type of specimens in the masonry strength. It has been accepted by the masonry community that the difference in elastic properties of the unit and mortar is the precursor of failure in compression, with uniaxial compression of masonry leading to a state of triaxial compression in the mortar and of compression/biaxial tension in the unit. Uniaxial compression tests in the direction parallel to the bed joints have received substantially less attention from the masonry community. However, regular masonry is an anisotropic material and, particularly in the case of low longitudinal compressive strength of the units due to high or unfavorable perforation, the resistance to compressive loads parallel to the bed joints can have a decisive effect on the load-bearing capacity.

The constitutive behavior of masonry under biaxial states of stress cannot be completely described from the constitutive behavior under uniaxial loading conditions. The influence of the biaxial stress state has been investigated up to peak stress to provide a biaxial strength envelope, which cannot be described solely in terms of principal stresses because masonry is an anisotropic material. Therefore, the biaxial strength envelope of masonry must be described either in terms of the full stress vector in a fixed set of

material axes or in terms of principal stresses and the rotation angle between the principal stresses and the material axes.

Summary

Masonry is a building material with many variations and different levels of success in modern construction worldwide. Masonry is also widely available in the built heritage, as most of the pre-twentieth-century buildings are made of masonry. Masonry consists of units laid with a certain bond, usually including mortar in the joints. Masonry can be typically unreinforced or reinforced and an understanding of this composite material requires the characterization of its components. Because masonry is a composite material, different modeling strategies are available either with the discretization of the bond or not. These approaches are denoted by micro- and macro-modeling, usually combined with advanced nonlinear analysis tools. Adequate seismic design and simple assessment of unreinforced masonry buildings are a challenging task and the applicability of the methods depends on the existence of box behavior for the building. In the absence of box behavior, macro-block analysis is a popular and powerful approach. Finally, it is noted that adequate characterization of the experimental behavior is needed for an effective analysis and design of masonry structures, and this is currently available in the literature.

Mechanisms of Earthquakes in Aegean

Anastasia A. Kiratzi

Department of Geophysics, Aristotle University of Thessaloniki, Thessaloniki, Greece

Synonyms

Fault-plane solutions; Focal mechanisms; Moment-tensor solutions

Introduction

Definition of Basic Concepts

The **focal mechanism** illustrates the geometry of faulting during an earthquake. For a fault-related earthquake, the focal mechanism describes the orientation of the causative fault (its strike and dip angle) and the direction of the slip on its plane (rake angle). The pattern of the radiated seismic waves depends on the fault geometry, thus the focal mechanism is determined from seismograms recorded at various distances and azimuths from the seismic source. The simplest method relies on the first-motion polarity of body waves, and the more sophisticated methods are based on waveform modeling of body and surface waves. Fault-plane solutions are described by two

Mechanisms of Earthquakes in Aegean,
Fig. 1 (a) Fault geometry used in earthquake studies, characterized by the strike, dip, and rake angles of the fault plane; (b) beach-ball presentation of focal mechanisms for the three major fault types

mutually orthogonal planes in space, one of which is the fault plane and the other is the auxiliary plane, to which the slip vector is normal. There is an ambiguity in identifying the fault plane on which the slip occurred, from the orthogonal, mathematically equivalent, auxiliary plane. The ambiguity can be resolved using additional information, for example, if the fault reaches the surface, if the aftershocks define a clear pattern which is aligned with one of the two nodal planes, and if directivity effects could be identified.

The fault geometry is shown in Fig. 1a. The fault plane is characterized by its normal vector. The direction of motion is given by the slip vector which is supposed to lie in the fault plane, so it is perpendicular to the normal vector. The slip vector indicates the direction in which the upper block of the fault, e.g., the hanging wall block,

moved with respect to the lower block, e.g., the footwall block. In the coordinate system adopted (Fig. 1a), the parameters used to describe the focal mechanism are: (a) the strike, ϕ , which is the angle between the trace of the fault (the intersection of the fault plane with the horizontal) and North ($0^\circ \leq \phi \leq 360^\circ$) (the strike angle is measured in such a manner so that the fault plane dips to the right-hand side); (b) the dip, δ , which is the angle between the fault plane and the horizontal at a right angle to the trace ($0^\circ \leq \delta \leq 90^\circ$); and (c) the rake, λ , which is the angle between the direction of relative displacement or slip and the horizontal measured on the fault plane ($0^\circ \leq \lambda \leq 360^\circ$).

The three major fault types e.g., reverse dip slip (reverse faults that dip at shallow angles $\sim <45^\circ$ are called thrusts), normal dip slip, and strike-slip are described by their corresponding

focal mechanisms, providing the values of these three angles, e.g., the strike, the dip, and the rake. The focal mechanism solution is typically displayed graphically using the so-called beach-ball diagram (Fig. 1b). The beach ball hints the stress-field orientation at the time of rupture, and the basic fault types can be related to the orientation of the principal stress directions. The tension axis (T) and the pressure axis (P) tend to approach the minimum and the maximum principal compressive stress directions, respectively, of the stress tensor. They coincide in the case the fault surface corresponds to the plane of maximum shear. The principal stress directions can be obtained by the inversion of fault-plane solutions. The T- and P-axes are determined from an eigenvalue and eigenvector analysis of the moment tensor. Since this tensor is symmetric, its eigenvalues are real, and its eigenvectors are mutually orthogonal, forming the set of T, P, and N (null) axes.

The Aegean

The Aegean Sea and the surrounding lands, mainland of Greece, southern Balkans, and western Anatolia, hereafter referred to as the Aegean, exhibit active deformation as manifested by the record of intense earthquake activity (the area hosts more than 60 % of the total European seismicity). Active tectonics apart from forming magnificent landscapes also provide a wealth of data to the geoscientists. To this end, the Aegean, even though it covers a small area in eastern Mediterranean, roughly $700 \text{ km} \times 700 \text{ km}$, is listed among the best studied regions of continental deformation and is often called a *natural geophysical laboratory*.

The major kinematic boundary conditions within the eastern Mediterranean are sketched in Fig. 2 and outline the following:

- The northward movement of the African (Nubia) plate relative to the Eurasian plate

Mechanisms of Earthquakes in Aegean, Fig. 2 A sketch of the major kinematic boundaries within eastern Mediterranean, with the rates of motion relative to

Eurasia. CTF Cephalonia transform fault zone, AFZ Achaia fault zone, PTF Pafos transform fault zone (Figure modified from Papazachos et al. 1998)

(convergence rate between 5 and 10 mm/year) and the subduction of its frontal part beneath the overriding Aegean lithosphere. The subduction rate exceeds the convergence rate, because of the rapid SW motion of the southern Aegean relative to Eurasia which leads to a subduction rate of ~ 35 mm/year; in this setting, the overriding Aegean plate must extend to compensate for the difference between the subduction rate and the convergence rate.

- (b) The westward motion of Anatolia relative to Eurasia, toward the Aegean, driven by the N-S convergence (at a rate of 30–40 mm/year), between the Arabian plate and Eurasia. This lateral extrusion of Anatolia, as a coherent rigid block, is facilitated by the operation of two strike-slip faults: the right-lateral North Anatolian Fault (NAF), with a slip rate ~ 24 mm/year and the more diffuse left-lateral East Anatolian Fault (EAF), with a slip rate ~ 9 mm/year (McClusky et al. 2000). The presence of the Hellenic subduction allows the Aegean plate to easily override the retreating subduction boundary.
- (c) The collision of the Adria–Apulia block with Eurasia along the western coastal region of Albania and western Greece.

In this geodynamic context, the deformation is distributed and is taken up by a number of faults, of variable length and orientation, on land and offshore, as illustrated in Fig. 3. Major fault segments are populated by families of minor faults forming wide zones of distributed faulting.

The Hellenic Subduction Zone

The Hellenic subduction zone (Jolivet et al. 2013; Ring et al. 2010) extends (Fig. 3) from approximately south of Zakynthos in the west up to Rhodes Island in the east. South of Crete, there is the *Mediterranean Ridge* which is the accretionary prism formed by the pile of sediments, up to 10 km thick that overlies the oceanic crust. The *Hellenic Trench* is a scarp in the bathymetry 2–3 km high, which is more clearly developed

in the western part of the subduction zone, between Peloponnese and Crete, while it splits into branches toward the east, the best developed of which are known as the *Ptolemy*, *Pliny*, and *Strabo Trenches*. After the recognition that the Mediterranean Ridge is an accretionary complex, it became apparent that the Hellenic Trench can be better understood as sediment-loaded fore-arc basin or else as a backstop to the deformed accretionary complex. The Hellenic Trench does not define the plate boundary, as it is common in other ocean trenches; it is not the surface projection of the subduction interface. The African–Aegean plate boundary itself lies south of the Mediterranean Ridge or very likely is buried beneath it. This can be easily understood from an assumption and simple geometry. Assuming that the low-angle thrusts, underlying the Hellenic Trench at depths up to 40–50 km, represent the interface between the subducting African lithosphere and the overriding Aegean plate, then their surface projection should be sought at least 150 km south of Crete at the Mediterranean Ridge. The degree of coupling on the Hellenic subduction interface, i.e., the fraction of the motion across the plate boundary accommodated by elastic strain accumulation, is estimated to be low (10–20 % of the full African–Aegean convergence rate).

The *Aegean Volcanic Arc* (Fig. 3) extends from Methana on the eastern coast of Peloponnese to the Nisyros Island in the east, close to coast of western Anatolia. The Hellenic Trench, the south Aegean Volcanic Arc, and the back-arc sea are the tectonic elements of the *Hellenic Arc*, which exhibits a strong curvature. It must be noted that in the present work, the back-arc area refers to the region behind the south Aegean Volcanic Arc and the fore-arc area refers to the region in front of the south Aegean Volcanic Arc (toward Crete). The identification of the Wadati–Benioff zone in the Hellenic Arc has been accomplished since the early 1970s (Papazachos and Comninakis 1971) and was subsequently better defined (Papazachos et al. 2000). This zone is relatively flat ($\sim 16^\circ$) beneath Peloponnese, has an average dip of 30° beneath Crete, and is steeper (50°) in the eastern part, near Rhodes Island.

Mechanisms of Earthquakes in Aegean, Fig. 3 Major tectonic structures in the Aegean, which are discussed in the text. The fault lines (available from the database of

Basili et al. 2013) are plotted aiming to show that in this tectonic setting, the deformation is distributed along wide zones including major and minor fault segments

The present work is focused on the earthquake focal mechanisms of the Aegean and the information they provide on the faulting characteristics and the regional stress field. Thus, in the sections that follow, a brief background on the sources of focal mechanisms for earthquakes in the Aegean is presented. Then, the available focal mechanisms are classified depending on the faulting type, and the general pattern of the spatial distribution of each category is presented. A number of features of specific interest are discussed in more detail, for

the region between the meridians 19–28°E and the parallels 34–41°N, even though in a number of cases broader regions are included in the figures.

Published Earthquake Focal Mechanisms in the Aegean: Historical Background

The published focal mechanisms for the Aegean follow the worldwide advances in instrumentation

and computational methods. In a global scale, the period 1962–1976 marks the era of analogue records, and from 1976 onward, the digital era takes place. In a regional scale, the first seismograph in Greece was installed in Athens in 1911 and marks the era of instrumental seismology for the Aegean. In mid-1960s, the World-Wide Standardized Seismographic Network (WWSSN) was established which provided high-quality analogue seismograms to the scientific community. These data were collected at Lamont–Doherty Observatory and at the United States Geological Survey (USGS) in Denver and Golden, Colorado.

By the 1980s, WWSSN was upgraded to form the 150+ station Global Seismographic Network (GSN), which currently has substantial capability in recording a broad spectrum of motions from Earth tides to local ground noise. Nowadays, free access to three-component broadband time series of ground motion is provided by the International Federation of Digital Seismograph Networks (FDSN), through the IRIS Data Management System (iris.edu/data). The advent of digital seismology together with the subsequent theoretical and computational advances in calculating synthetic seismograms increased the number of the published earthquake focal mechanisms worldwide as well as for the Aegean area. Thus, since 1976, nearly all earthquakes with $M_w > 5.5$ have a published solution based on waveform modeling.

Over the years, the published earthquake mechanisms for the Aegean have been determined using different methods and waveforms, which are briefly presented in the following section.

Focal Mechanisms Determined from First-Motion Polarities

These are focal mechanisms of Aegean earthquakes determined from the first-motion polarity of P-waves. From the published first-motion solutions, more reliable are those for which (a) the first P-wave polarity was read on long-period instruments, preferably on the WWSSN 15–100 s instruments, and (b) the observed polarity distributions are also published. Long-period records are generally less noisy, so the polarity is clearer to read, while the publication of the

observed polarities provides the means to evaluate the solution, judging from the number of the polarities, the azimuthal distribution of the stations used, and the number of nodal readings that constrain the orientation of the nodal planes, to mention a few criteria. Depending on the distribution and quality of first-motion data, more than one focal mechanism solution may fit the data equally well (see, e.g., the compilation by Udias et al. 1989). From the first-motion solutions which are available for Greece, a significant number include focal mechanisms for small and moderate magnitude ($M < 5$) earthquakes and aftershock sequences, recorded by temporary networks. These were installed in mainland Greece and the islands, in the framework of a series of projects, mainly in the decades from 1980 to 2000 (e.g., Hatzfeld et al. 1990). First-motion polarity solutions for earthquakes in the Aegean remain an important database even though their significance was later surpassed by the solutions obtained using waveform modeling.

Focal Mechanisms Determined from Waveform Modeling at Teleseismic Distances

These are focal mechanisms of Aegean earthquakes determined by the computation of synthetic seismograms that best fit the observed seismograms at teleseismic distances in the range of 30° – 90° . The technique is known as waveform modeling, and synthetics are calculated using a ray theory approach, a well-known code is MT5 (Zwick et al. 1994), usually referred to as *body-wave analysis*, or on a normal-mode approach commonly referred to as *centroid moment tensor* or CMT analysis. The main tenet in both approaches is to use wavelengths of seismic waves that are longer compared to the earthquake source dimensions (i.e., the fault length). If this is fulfilled and if the source-station separation is larger than the fault length, then the source appears as a point in space (the so-called centroid) even though it may have finite time duration. In a number of cases, the point-source approximation is not valid. For example, when the observed waveforms support the existence of discrete sub-events, then the contribution of these sub-events can be modeled introducing a number

of separate sources appropriately lagged in space and time. Well-known source for CMT solutions is the Global CMT Project (globalCMT.org), formerly known as Harvard CMT catalog (Ekström et al. 2012). Other sources include the body-wave moment-tensor solutions, which have been reported from the United States Geological Survey since 1981 (Sipkin 1994).

There are differences in the previous inversion schemes. In the body-wave analysis, the focal mechanisms are constrained to be double-couple solutions (i.e., to result from slip on a fault). The window of data examined in the inversion is short; it includes the first part of the P and SH (horizontal component of S-wave) waveforms. For example, for shallow earthquake sources, the data window examined usually ranges from ~ 20 to 40 s and allows the inspection of relatively high frequencies. Focal depths constrained by the so-called depth phases, pP and sP, which leave the source upward, are reflected at the free surface and continue further as P-waves. To identify the separation between P and pP or sP is more difficult the shallower the source. For example, for depths in the range 10–20 km, the time separation between P and pP and between P and sP is of the order of 4–10 s. Commonly, during the processing stage of digital waveforms from the modern global networks, after removing the instrument response, the waveforms are convolved with the response of the old long-period WWSSN 15–100 instruments (with a peak response at ~ 15 s), because it provides a frequency range suitable for the inversion.

The CMT method is based on the linear relationship that exists between the six independent elements of a zeroth-order moment-tensor representation of an earthquake and the ground motion that the earthquake generates. The “centroid” of the CMT method refers to the center of the earthquake moment distribution in time and space, defined by four additional parameters. Ten parameters (six moment-tensor elements and the centroid latitude, longitude, depth, and centroid time) thus provide the point-source CMT representation of an earthquake. No volumetric component is allowed in the moment tensor, and the published focal mechanisms are constrained to be

purely deviatoric. Longer time windows are used compared to the time windows used in the classic body-wave analysis. For the typical $5.5 \leq M_w \leq 6.5$ Aegean earthquakes analyzed, the body waves are filtered to displacement between 150 and 40 s, with a flat response between 100 and 50 s. In a number of cases, the CMT inversions cannot sufficiently resolve the spatial centroid of the source, in particular the focal depth for shallow sources. Thus, in the GCMT catalog, sometimes the focal depth is fixed, when the inversion attempts to place the source above the minimum allowed depth of 12 km or when the depth exhibits persistent instability in the inversions.

Focal Mechanisms Determined from Waveform Modeling at Regional Distances

These are focal mechanisms of Aegean earthquakes determined by waveform analysis, moment-tensor inversion from body waves (Dreger 2003; Sokos and Zahradnik 2008), and centroid moment-tensor inversion, using ground motion records from broadband sensors at regional distances. The trick in this methodology is to use long-period regional-distance seismic waves. The source process can be reduced to a simple delta function “spike” in space and time. The wave propagation is also simplified because filtering regional seismograms to long periods (or low frequencies) results in waves that have only propagated in a few wave length cycles and can be predicted using relatively simple one-dimensional layered Earth models. Canceling out all of these complex effects leaves the robust extraction of the radiation pattern. A more generalized moment tensor can be solved with simple constraints added e.g., that the source has no isotropic component, although this constraint is not valid when estimating the moment tensor of volcanic sources.

The Era of Real-Time Focal Mechanisms in the Aegean

Seismic instrumentation in Greece was gradually upgraded to obtain its present-day configuration which counts 200+ broadband sensors in operation. The funding to the Greek seismological

Mechanisms of Earthquakes in Aegean, Table 1 Classification of the Aegean focal mechanisms based on the plunge of P, T, and N stress axes (After Zoback 1992)

Plunge (pl) of axes			Faulting type
P-axis	T-axis	N-axis	
$pl \geq 52^\circ$	$pl \leq 35^\circ$		Normal faulting [NF]
$40^\circ \leq pl < 52^\circ$	$pl \leq 20^\circ$		Normal oblique faulting [NS]
$pl \leq 35^\circ$	$pl \geq 52^\circ$		Thrust faulting [TF]
$pl \leq 20^\circ$	$40^\circ \leq pl < 52^\circ$		Thrust oblique faulting [TS]
$pl < 40^\circ$	$pl < 40^\circ$	$pl \geq 45^\circ$	Strike-slip faulting [SS]

community usually increases in the aftermath of a strong event, thus the seismological networks were mainly upgraded after the Athens 1999 earthquake. The establishment of the Hellenic Unified Seismological Network (HUSN) marks the beginning of a new era for instrumentation coverage in Greece (see <http://bbnet.gein.noa.gr/HL/> for network geometry). Four centers constitute the core members of HUSN: (a) the Geodynamic Institute of the National Observatory of Athens (NOA), (b) the Seismological Laboratory of the Aristotle University of Thessaloniki (AUTH), (c) the Seismological Laboratory of Patras University (UPSL), and (d) the Seismological Laboratory of Athens University (UOA).

In late 2005, these Greek seismological agencies began a systematic determination of moment-tensor solutions for strong earthquakes, and these solutions are transmitted to the European-Mediterranean Seismological Centre (EMSC-CSEM/). They can be retrieved from the following website using the code of each institute (<http://emsc-csem.org>).

Gross Features of the Spatial Organization of the Aegean Mechanisms

In the following sections, the spatial organization of earthquake focal mechanisms in the Aegean is discussed, using data from published sources and for earthquakes after mid-1950s mainly with $M_w \geq 5.5$. For the period 1950–1959, the focal mechanisms are mainly from first-motion polarities. Even though smaller magnitude events are usually not a good proxy for regional tectonics, in

a number of cases, they are included in the plots for emphasis to some patterns. To classify the focal mechanisms, the criteria listed in Table 1 were used. Focal mechanisms from shallow-focus ($h \leq 50$ km) earthquakes and deeper than 50 km are examined separately. This cutoff depth, even though arbitrarily chosen, provides a useful depth range, because the deeper than 50 km earthquake mechanisms are all confined within the subducting African lithosphere.

It should be noted that the maximum depth of earthquakes within the lithosphere, which defines the thickness of the seismogenic layer, is of the order of 10–20 km in the Aegean. This thickness provides a scale for the dimensions of active structures, as well. Earthquakes which are strong enough to rupture the entire thickness of the seismogenic layer are produced from large faults. Moderate-size events with ruptures confined within the seismogenic layer are produced from smaller faults (Jackson 2001).

Figure 4a–d summarize the classification of the shallow ($h \leq 50$ km) focus and intermediate ($h > 50$ km) focus earthquake focal mechanisms, respectively, into three major categories: reverse/thrust faulting, normal faulting, and strike-slip faulting. Some general features are summarized below, while selective features of the spatial organization of the focal mechanisms, in all cases for shallow-focus events, are discussed in more detail in the following sections.

The Zone of Thrust/Reverse Faulting

The Thrust Zone Along the Adria: Eurasia Convergence

Thrust faulting (Fig. 4a) dominates the foreland and hinterland flanks of Albania, where the

Mechanisms of Earthquakes in Aegean, Fig. 4 (continued)

M

Mechanisms of Earthquakes in Aegean, Fig. 4 (continued)

collision of Adria–Eurasia occurs. The active thrust front is related with (a) low-angle thrusting ($<35^\circ$) toward the coastal region, which extends to depths up to 30 km, and (b) steeply dipping ($>35^\circ$) reverse type faulting, probably blind, which is overlain by anticlines, clearly visible in the topography. In the anticline geometry, the large thickness of salt formations plays a significant role (Copley et al. 2009). The majority of earthquakes are connected with the low-angle thrust faults, and fewer are connected with the steeper reverse faults (Kiritzi and Louvari 2003; Tselentis et al. 2006).

The zone of thrusting from Albania continues southward (Fig. 4a), through the coast of western Greece, along the inner east coast of the Ionian Islands and connects south of Zakynthos Island with the western termination of the Hellenic subduction zone. This thrusting is mainly along N-S trending planes, with slip vectors trending E-W. High-resolution seismic images of P- and S-wave velocity perturbations, across a line that starts from Corfu and crosses western and central Greece, provide new evidence that continental crust is subducting below northern Greece (Pearce et al. 2012) in contrast to the oceanic crust subducting between Peloponnese in the south. The images show a ~ 20 km thick low

velocity layer (LVL) dipping at $\sim 17^\circ$ within the upper mantle beneath northern Greece. It is interpreted as subducted continental crust. This interpretation requires that ~ 8 km of sediments have been scraped from the subducting slab and have been accreted into the thrust belt of the overriding plate, in accordance with previous results (Royden and Papanikolaou 2011). This is required because marine seismic data indicate that the thickness of the continental crust within the foreland is ~ 28 km, consisting of ~ 20 km of crystalline crust overlain by ~ 8 km of sediments. The low seismicity level between Africa and Apulia and the very similar pattern of the subducted slab north and south of the Cephalonia transform fault support the model of a continuous slab from north to south (Pearce et al. 2012). This continuity and the offset induced by the Cephalonia transform fault would provide a lateral ramp geometry for this fault (Shaw 2012) instead of a slab tear.

The Thrust Zone Along the Africa–Eurasia Convergence Zone

South of Zakynthos Island and up to Rhodes Island and the southern coast of western Anatolia, the thrust and reverse faulting reflects the African–Aegean collision (Fig. 4a). The

M

Mechanisms of Earthquakes in Aegean, Fig. 4 Spatial organization of earthquake focal mechanisms in the Aegean (the size of the beach-ball scales with magnitude). Data were classified into the three major fault types, based on the plunges of the principal axes, and are presented for shallow ($h \leq 50$ km) and deeper sources, separately. The data included in the figures are for earthquakes with $M_w > 4$ which occurred in the period 1950–2013, with the smaller magnitude events to span the most recent years. From 1960 onward, most of the mechanisms have been determined with waveform modeling. (a) Reverse/thrust faulting in the Aegean along the subduction zones. In western Albania and Greece, the compression reflects the Adria–Eurasia collision zone; south of Zakynthos Island, the compression reflects the African–Aegean convergence. Sparse thrusting in northern Greece is also evident together with the focal mechanism for the event of 3 March 1969 M_w 5.8, south of the North Anatolian Fault, which probably reflects

contractional irregularities on strike-slip faults. (b) Normal faulting in the Aegean. Dark-shaded beach balls denote the N-S extension in the back-arc region (as defined here), whereas the light-shaded beach balls denote the $\sim$ E-W intra-mountain extension (Hellenides Mts) which connects with the along-arc extension that the overriding Aegean plate undergoes, south of the volcanic arc. (c) Strike-slip faulting in the Aegean discussed in more detail in the text. (d) Distribution of intermediate-depth ($h > 50$ km) earthquake focal mechanisms ($M_w > 5.5$), whose depths are also plotted. They are all confined within the subducting African slab which undergoes along-arc compression. The majority of the data show strike-slip and reverse/thrust faulting, with the deepest events in the eastern part of the subduction. The two cross sections depict the steeper dip angle of the subduction in the eastern edge compared to the central part. The seismicity plotted (dots) is from HypoDD relocated events and from field experiments

earthquakes along this zone follow the bathymetry of the Hellenic Trench and show a tendency, at least during the years of observation, to form dense discrete clusters, separated by areas with no strong earthquakes, as, for example, south of Peloponnese and Crete. The low-angle landward dipping planes are the fault planes, and the P-axis is orthogonal to the subduction interface in its western margin and parallel to it, due to arc-oblique convergence in its eastern termination.

The Zone of Normal Faulting

E-W Extension Along the Albanides: Hellenides Mountainous Chains

There is a distinct zone of $\sim$ N-S normal faulting (Fig. 4b – light-shaded beach balls) that runs along the mountainous area of eastern Albania and continues in the mainland of Greece, along the backbone of Hellenides Mountains. The $\sim$ E-W extension along this zone is perpendicular to the long axis of the mountains. There is evidence that this N-S normal faulting reaches the surface. This can be deduced from the shape of a number of intra-mountain basins, as, for example, Lake Ohrid, which has the characteristic shape of a normal fault-bounded basin, and from the surface expression of the faults at its southern end in NW Greece (Goldsworthy et al. 2002).

E-W Extension Along the Southern Part of the Overriding Aegean Plate (Fore-Arc)

South of the Volcanic Arc in southern Aegean, the distribution of the focal mechanisms reveals a broad zone of N-S normal faulting (Fig. 4b – light-shaded beach balls). It was first identified in western Crete and Peloponnese (Lyon-Caen et al. 1988), but as the focal mechanism database enriches, it is evident that this E-W extension is the dominant mode of deformation within the entire southern part of the overriding Aegean plate.

N-S Extension Along Mainland Greece and Western Anatolia (Back-Arc)

The back-arc Aegean and western Anatolia are dominated by normal faulting along roughly E-W

trending planes. This is the dominant mode of faulting (Fig. 4b – dark-shaded beach balls), which is frequently combined with a considerable strike-slip component. The dip angle of the nodal planes (both planes considered) is in the range of 30 – 65° with an average value of $\sim 50^\circ$. The age of the onset of the back-arc Aegean extension is from 15 to 45 Ma, depending on the author and the data used to define it (as, e.g., normal faulting bounding sedimentary basins, metamorphic core complexes in central Cyclades islands). For ~ 30 Ma, only back-arc extension driven by slab rollback was dominant. The interaction between the back-arc Aegean extension and the westward extrusion of Anatolia initiated around 13 Ma ago (middle Miocene) and dominates the Aegean tectonics ever since. It is worth mentioning that since the 1970s, the extension in the Aegean has been connected to the sedimentary basin formation (McKenzie 1978) and to the subduction process itself (Le Pichon and Angelier 1979).

The Zone of Strike-Slip Faulting

The Shallow-Depth Strike-Slip Fault Zones

Figure 4c shows all earthquakes with strike-slip focal mechanisms. It is evident that there are several narrow zones which accommodate shear motions, and in general, the NE-SW trending structures are associated with dextral strike-slip motions, whereas the NW-SE trending ones are associated with left-lateral strike-slip motions. In eastern Aegean Sea, the strike-slip zones reflect the shear transmitted from the east, and the major and minor segments of the North Anatolian Fault are well outlined. The strike-slip faulting reaches Evia Island but it does not cross central Greece. In western Greece, the most striking feature is the wide strike-slip zone which covers the Ionian Islands and western Peloponnese. North of $\sim 40^\circ$ parallel, the sparse strike-slip faulting is mainly confined at the edges of major normal faults. It is worth noting here the abundant strike-slip faulting along the Hellenic arc, which follows bathymetric lineaments. It is more evident at its eastern termination from the occurrence of a few strong events.

Mechanisms of Earthquakes in Aegean, Fig. 5 Development and continuation of ~E-W normal faulting bounding graben structures and basins in the region extending from the Gulf of Corinth to the Gulf of

Evia, as discussed in the text. In this and the following figures, the dates for all earthquakes with $M_w \geq 5.9$ are shown next to the beach balls

The Intermediate-Depth Mechanisms Within the Subducting African Lithosphere

Figure 4d summarizes the focal mechanisms for the intermediate-depth ($h > 50$ km) earthquakes ($M_w > 5.5$), which are all confined within the subducting African plate. These focal mechanisms indicate reverse faulting with considerable strike-slip component or pure strike-slip faulting. Evidently, the subducting African slab undergoes along-arc compression. The downdip length of the slab is approximately 300 km and reaches to a depth of about 160 km, as deduced from the results of field experiments (Hatzfeld and Martin 1992). There is a pronounced consistency regarding the P-axes, which, in general, are parallel to the local curvature of the subduction zone, whereas the T-axes are aligned downdip within the subducting slab (Benetatos et al. 2004). The deepest events are concentrated at the eastern part of the subducting slab, NW of Rhodes, where the slab has a steeper dip (see the cross sections in Fig. 4d), as was mentioned in the introduction.

In the following sections, special features of the earthquake focal mechanisms in the Aegean are discussed in more detail.

Characteristics of Normal Faulting in Mainland Greece

The prevalence of normal faulting in the mainland of Greece is manifested in a number of grabens and basins in central Greece, whose edges are bounded by large segmented normal faults, which in many cases are associated with impressive topographic escarpments. The maximum typical lengths of these fault segments are of the order of 15–25 km. In the following section, starting from south toward north, a number of these regions of significant normal faulting concentration are discussed.

The best studied region is the Gulf of Corinth (Fig. 5), an asymmetric graben (or rift) 100 km long, which ranks first among the rapidly extending regions in Greece. The geodetic measurements indicate a fast rate of 12–14 mm/year in the west part of the Gulf of Corinth and a slower rate of 6–8 mm/year in the eastern part. The present-day structure and kinematics of the Corinth Rift can be explained with a series of décollements relayed by steeper ramps that altogether formed a mechanically weak, crustal-scale detachment (Jolivet et al. 2010). The E-W normal

Mechanisms of Earthquakes in Aegean, Fig. 6 Development of WNW-ESE and E-W normal faulting in Thessaly, as deduced from focal mechanisms, mainly along the southern margins of the basins,

extending from Sofades to the Pelion Peninsula. Along this zone, a series of strong events occurred in the 1950s and 1980s (dates designated in the figure)

faulting observed in the Gulf of Corinth continues eastward through the Thiva basin and into the Gulf of Evia. In the family of faults within the broader region of this basin, the most recent earthquake activity occurred during February–March 1981 and on September 1999 earthquake sequence. Few mechanisms are available for strong earthquakes on Evia Island itself; however from a number of moderate-size events, there are indications of normal faulting along mainly E-W trending planes.

Further to the north in central Greece (Fig. 6), most of the available focal mechanisms are from earthquakes with epicenters along the southern side of the Karditsa and Larisa basins, between Sofades and Volos. These basins are bounded by normal faulting striking NW-SE or E-W.

In northern Greece, a region of pronounced normal faulting is the Mygdonian basin (Fig. 7) close to Thessaloniki, the second metropolitan city in Greece, after the capital, Athens. The basin between the Lagkada and Volvi Lakes shows the operation of nearly E-W trending normal faulting (Tranos and Lacombe 2014), which is considered more active and more recent and is

optimally oriented to the present-day stress field. One of these faults moved during the 1978 Mw 6.5 earthquake which produced significant losses to the city of Thessaloniki. The zone of E-W normal faulting close to eastern Thessaloniki is not clear if it continues westward, crossing the Gulf of Thermaikos. In this area, there is only moderate-size recent seismicity, with focal mechanisms predominantly showing strike-slip motions; however it is doubtful whether they reflect the regional tectonics. The epicenters of this modern seismicity are in the flood plain of the Axios and Aliakmon rivers, and the thick pile of sediments obscures field observations.

Further to the west, (Fig. 7) along the Ptolemais plains, the focal mechanisms indicate the operation of normal faulting along NE-SW trending planes, and the most well-studied event in this area is the 15, 1995, sequence between the cities of Grevena and Kozani. There are indications, from field observations and moderate-size seismicity, on the existence of gradually evolving network of distributed active normal faulting, between the Kastoria Lake and Vegoritis Lake (see also Fig. 3).

Mechanisms of Earthquakes in Aegean, Fig. 7 Development and continuation of normal faulting in northern Greece. Along the Mygdonian basin, there are abundant focal mechanisms that show development of

mainly E-W normal faulting, whereas in other parts of this region, the number of the available mechanisms is limited. Nevertheless, they do depict the acting stress field and the large-scale topography

M

Characteristics of Strike-Slip Motions in the Aegean

Strike-Slip Motions in Central and Eastern Aegean Sea

The main characteristics of the strike-slip faulting in the eastern Aegean Sea and Thrace are (Fig. 8) (a) its connection with topographic and bathymetric escarpments that run for several hundreds of kilometers and (b) its concurrent operation with normal faulting, which differs in orientation from the classic E-W trending faults characterizing the Greek mainland. The most prominent example for the latter is the normal faulting event of 19670304 Mw 6.6 in Skiros basin; this ENE-WSW extension orientation characterizes most of the normal faulting events in central Aegean Sea (Chatzipetros et al. 2013). It can be traced up to the three-leg Chalkidiki peninsula as deduced from a few moderate earthquake focal mechanisms.

In northern-eastern Greece, the Kavala-Xanthi-Komotini fault zone has a prominent

escarpment in the morphology, which suggests normal oblique faulting as the prevailing mechanism. Unfortunately, the instrumental seismicity and the available focal mechanisms are not sufficient to describe the type of faulting.

Along the eastern Aegean Sea, strike-slip faulting forms distinctive stands, which bound a number of basins/troughs, the most prominent of which are: (a) The North Aegean Basin (NAB) which consists a number of fault-bounded basins which extend from Saros bay in the east to the Sporades islands in the west. Moreover, along the NAB which accommodates a large part of the westward motion of Anatolia relative to Eurasia, the occurrence of strong events is abundant. (b) The Skiros- Edremit Trough and the Lesvos-Psara Trough, which are both the sites of several strong events. There is evidence from the bathymetry and the focal mechanisms of small magnitude events that the strike-slip faulting reaches the Cyclades Islands in the west.

The dextral strike-slip motions in the north and central Aegean Sea extend westward and

Mechanisms of Earthquakes in Aegean, Fig. 8 Distribution of strike-slip faulting in central and eastern Aegean Sea and regions of localized normal faulting within it, as discussed in the text. The arrows

indicate the polarity of shear motions, right-lateral in the central and eastern part and left-lateral near the interface with the mainland of Greece

terminate close to the mainly E-W striking normal faulting system that controls the eastern coastline of the Greek mainland. This transition from dextral NE-SW shear motion to E-W normal faulting is reflected in the azimuth of the slip vectors, which changes from NE-SW to N-S.

Strike-Slip Motions Near the Intersection with the Eastern Greek Mainland

The linkage of the strike-slip motions in eastern Aegean Sea with the normal faulting in mainland Greece has been an interesting field of research and debate. In this transition zone, the Sporades Islands and Evia Island have a key location (see Fig. 8).

One point that is worth mentioning is the presence of NW-SE trending structures, close to this transition zone, that are activated as strike-slip faults with left-lateral component and not dextral as in the eastern Aegean Sea.

The first well-recorded information for left-lateral strike-slip motions was from the 20010726 Skiros Island earthquake sequence (Fig. 8). A number of previous strong earthquakes, for example, the event of 19650309 in Sporades Islands, could be also connected with left-lateral strike-slip motions. A well-located seismic sequence in northern Evia, which burst in November 2013, provided additional evidence for left-lateral strike-slip motions.

In view of the above, the operation of these NNW-SSE trending structures as left-lateral strike-slip faults should be also taken into account in the discussions regarding the change in the direction of the slip vectors. It is also worth mentioning that this left-lateral strike-slip component along the western shoreline of the North Aegean Sea is well resolved in the GPS-derived strain field (Müller et al. 2013). The change of strike of the active structures from east to west, e.g., from NE-SW to east Aegean to NW-SE at the edge of the Greek mainland to E-W on the mainland itself, and the subsequent change in the direction of the slip vectors can be accommodated by clockwise rotations of the fault-bounded blocks in central Greece relative to Eurasia (broken-slats model of Taymaz et al. 1991).

Strike-Slip Motions in Western Greece

As previously mentioned, western Greece lies in the crossroads of continent–continent collision in the north and ocean–continent subduction in the south (Fig. 9). These two regimes are offset by ~100 km (Pearce et al. 2012) across the Cephalonia–Lefkada Transform Fault, whose existence has been postulated by McKenzie (1978). It is expressed as an abrupt lateral ramp in the bathymetry (Shaw 2012) approximately 4,000 m deep, between the Adriatic Sea and the Ionian Islands. Two segments have been identified along this fault zone, the 40 km long Lefkada segment and the 90 km long Cephalonia segment

(Louvari et al. 1999). This fault zone is very active, and this is the reason why the Hellenic Seismic Code is designed for the highest resistant constructions. Recently, on 26 January 2014, an Mw 6.1 seismic sequence burst on Cephalonia Island, followed by another Mw 6.0 event on 3 February 2014. The first event was connected with a N24°E and steeply dipping strike-slip fault, whereas the second event was connected with a N297°E and shallow dipping thrust fault. These thrust faulting events are not unusual in the Ionian Islands and are usually associated with severe ground shaking. This zone of thrusting follows the Ionian Thrust which is a major structural feature, a crustal-scale thrust fault (Kokkalas et al. 2013). It is worth noting that the 1953 earthquakes that destroyed the islands of Cephalonia and Zakynthos are associated with coastal uplift and thrusting mechanisms.

The strike-slip motions in western Greece cover a wide zone between the Ionian Islands and western Peloponnese. Strike-slip motions along the northwestern coast of Peloponnese have been already noticed in Louvari et al. (1999) and were confirmed by the occurrence of the 8 June 2008 Mw 6.3 Achaia earthquake. This event, which had a source depth of ~22 km, was the first strong event which provided evidence for a gradually developing right-lateral strike-slip zone, the Achaia strike-slip fault zone.

From a number of moderate-size earthquake focal mechanisms, there is evidence for left-lateral strike-slip motions, oblique to the main branches of the right-lateral shear. For example, such a left-lateral shear zone extends from Lake Trichonis toward Amfiloxia and the Gulf of Amvrakikos (Fig. 9), and its operation is supported by the morphology and a characteristic drainage pattern (Vassilakis et al. 2011).

This tectonic setting with distinct parallel branches of NE-SW right-lateral strike-slip faulting and oblique to it NW-SE left-lateral strike-slip faulting resembles the tectonic setting in central and eastern Aegean Sea, as it was previously discussed.

Mechanisms of Earthquakes in Aegean, Table 2 Typical focal mechanisms for normal/reverse/strike-slip type faulting in the Aegean, derived by summing magnitude-normalized moment-tensor components (for $M_w > 4$ and $h \leq 50$ km) of each category. The average depths provide a scale of the thickness of the seismogenic layer

The available focal mechanisms for earthquakes with $M > 4$ and for depths less than 50 km are not balanced in terms of the faulting type. The majority is for normal (40 %) and strike-slip (40 %) faulting and the remaining (20 %) is for reverse/thrust faulting. This crude quantification also reflects the dominant modes of deformation within the Aegean area. Taking this gross statistics a step further, Table 2 summarizes the typical focal mechanisms for each fault type, deduced by summing the moment-tensor components and normalizing for the magnitude.

Summarizing, the compression revealed by the distribution of the reverse/thrust faulting (Fig. 4a) is well confined in two regimes: (a) in the north, the collision of Adria and Eurasia takes place, and the active thrust front is confined in a narrow belt in the lowlands of Albania and western Greece; new evidence suggest that continental crust is subducting below northwestern Greece; (b) in the south, at the Ionian Islands, and southward the zone of low-angle thrusting follows the curvature of the Hellenic Trench and continues up to western Anatolia; this low-angle land dipping thrusting reflects the African–Aegean convergence; it does not mark the subduction interface itself, as this is projected south of the Mediterranean Ridge (very likely below the thick pile of sediments). These two subduction zones are separated by the Cephalonia–Lefkada Transform Fault.

~N-S extension (Fig. 4b) is confined in continental Greece and western Anatolia. Within the Aegean Sea itself, the extension is localized, and its orientation is mainly ENE-WSW. In central Greece, the extension is accommodated by slip along families of normal fault segments.

The major and most prominent faults bound the southern part of a series of grabens. The Gulf of Corinth and the Gulf of Evia are good examples of this geometry.

~E-W extension (Fig. 4b) occurs along a distinct belt which can be traced all the way from the mountainous inner Albania, through the backbone of the Hellenides Mountains, spreading along the southern Aegean and ending in western Anatolia. In Albania and northwestern Greece, the zone of E-W extension is subparallel to the outer zone of thrusting and is attributed to contrasts of the gravitational potential energy, between the high mountains in the west and the lowlands of western Albania and the Adriatic Sea. E-W extension occurs south of the Volcanic Arc, in the southern Aegean Sea and Crete itself, and reflects the deformation within the overriding Aegean plate. The boundary, if any, between these two extensional regimes of similar orientation should be sought somewhere south of the 38° parallel where the signature of the subduction process begins to emerge.

Strike-slip faulting (Fig. 4c) is abundant in the Aegean especially in its eastern and western edge. Shear motions tend to develop in parallel strands. For example, in eastern and central Aegean Sea (Fig. 8), the best developed and more clearly related to the prolongation of the North Anatolian Fault into the Aegean is the strike-slip faulting along the North Aegean Basin (or else North Aegean Trough). The right-lateral shear ends abruptly at the western edge of the Greek mainland, near the Sporades Islands and Evia Island. New evidence from modern strong events suggests that along this interface, left-lateral strike-slip faulting is taking place,

which is further supported by updated versions of the GPS-derived strain field (Müller et al. 2013). In brief, as previously suggested depending on the fault strike, the present deformation field allows for both right-lateral and left-lateral shear motions (Kiritzi 2002).

The shear imposed from the Anatolia extrusion passes central Greece as it is depicted by the orientation of the earthquake slip vectors, which alter from being parallel to the shear motions to become approximately N-S. Clockwise rotations of the fault-bounded blocks in central Greece relative to Eurasia (broken-slats model of Taymaz et al. 1991) provide a suitable kinematic mechanism to explain this change in the orientation of the slip vectors.

The shear motions which pass the Greek mainland are accommodated in the western Aegean margin in a similar pattern as in central and eastern Aegean Sea (Fig. 9). This is evidenced by the wide zones of strike-slip faulting which develop, again in parallel strands, along the western coasts of the Ionian Islands and western Peloponnese. These strike-slip faults are mechanically necessary in order to transport the strain and act as planes of weakness. The right-lateral Cephalonia-Lefkada and the more immature Achaia strike-slip fault zones are well resolved from modern strong events.

There are indications, from moderate-size events, for left-lateral strike-slip faulting along two zones: (a) one extending from the Gulf of Patras and Lake Trichonis up to Amfiloxia, following the NNE-trending Amfiloxia fault zone (Kiritzi et al. 2008) and (b) one extending from Pirgos in western Peloponnese up to Zakynthos Island (see Fig. 9 for locations). These two strands are not yet well documented from the occurrence of strong events.

Regarding the intermediate-depth ($h > 50$ km) earthquake focal mechanisms, these are all confined within the subducting Africa slab (see Fig. 4d). The azimuths of the P-axes are consistently parallel to the local trend of the Hellenic arc showing along-arc shortening. The azimuths of the T-axes are radial to the arc and are aligned with the dipping slab (Benetatos et al. 2004).

In conclusion, the earthquake focal mechanisms in the Aegean most of the times reveal remarkable uniformity, order, and kinematic links. They provide the most significant tool to study present-day tectonics and the key to study past tectonics.

Data Sources

The data used in this work have been all retrieved from published sources, especially for the stronger earthquakes. A number of focal mechanisms from smaller magnitude events are from the author's unpublished work. Most of the figures were produced using the GMT software (Wessel and Smith 1998).

Mechanisms of Earthquakes in Iceland

Páll Einarsson

Institute of Earth Sciences, University of Iceland, Reykjavík, Iceland

Synonyms

Bookshelf faulting; Divergent plate boundaries; Hreppar microplate; Seismicity of Iceland; South Iceland Seismic Zone; Tjörnes fracture zone; Transform zones; Volcanic earthquakes

Introduction

Most of the seismicity of Iceland is due to processes related to the mid-Atlantic plate boundary that crosses the country (Fig. 1). These processes include transform faulting, rifting, dike injection, inflation and deflation of magma chambers, cooling of magma bodies, and volume changes of geothermal fluids (Einarsson 1986, 1991, 2008; Sigmundsson 2006).

South of Iceland the seismically active belt follows the axis of the Reykjanes Ridge, and north of the country it follows the Kolbeinsey Ridge. On both ridges the seismicity decreases toward Iceland. This may be due to the existence of the Iceland hotspot, an area of high topography and heat flow, a result of excessive volcanism. The excessive volcanism produces a relatively thick crust of elevated temperature gradient. Combined with the spreading of the plates away from the plate boundary, the thick crust forms a complex of submarine highs extending between Scotland and Greenland (Fig. 1). The spreading velocity along the plate boundary is relatively low, less than 2 cm/year. Yet the topography of the ridge segments near Iceland, Reykjanes and Kolbeinsey Ridges, shows characteristics of fast-spreading ridges. Near its southern end, 53–59°N, on the other hand, the Reykjanes Ridge has the characteristics of a slow-spreading ridge, rough topography, deep rift valley, and relatively high seismicity. North of 59°, the fast-spreading characteristics become more prominent (Einarsson 2008). There is no direct evidence for faster spreading, however. Magnetic anomalies show spreading rates of 18–20 mm per year in a direction of 105°, corresponding to the distance to the Euler pole between the North America and Eurasia plates that is located in Siberia (Einarsson 2008; Sigmundsson 2006).

The plate boundary on Iceland is expressed by a series of seismic and volcanic zones. Two transform zones connect the presently active Northern and Eastern Volcanic Zones to the ridges offshore (Fig. 2). The transform zones host the largest earthquakes in the area, as large as magnitude 7, whereas the volcanic rift zones produce only smaller earthquakes, rarely exceeding magnitude 5.5.

Mechanisms of Earthquakes in Iceland, Fig. 1 Epicenters in Iceland and along the Mid-Atlantic Ridge system 1964–2004. Data are from the catalogs of the International Seismological Centre. Bathymetry is

from General Bathymetric Chart of the Oceans (Modified from Sólmes et al. (2013) with help from Gunnar B. Guðmundsson at the Icelandic Meteorological Office)

The structure of the plate boundary is strongly influenced by the Iceland mantle plume presumed to be centered beneath central Iceland. The plume is thought to have a deep root in the mantle, and its upwelling leads to the production of the magma that feeds the volcanoes of the hotspot. The relative motion of the Mid-Atlantic Ridge with respect to the plume leads to ridge jumps, propagating rifts and other complexities (e.g., Einarsson 1991, 2008). A new rift zone is initiated when the old rift has migrated some critical distance off the plume center. The transform zones are also

unstable and respond to changes in the configuration of the rifts.

Seismic and Tectonic Characteristics of Seismic Areas

Plates, Microplates, and Boundaries

The mid-Atlantic plate boundary is relatively simple in most parts of the NE Atlantic consisting of rifting and transform segments separating the two major plates, Eurasia and North America.

Mechanisms of Earthquakes in Iceland, Fig. 2 Volcanic systems of Iceland and epicenters located by the local seismic network in the period 1994–2006. The volcanic systems are from Einarsson and Sæmundsson (1987) and the seismic data from the Icelandic Meteorological Office. The fissure swarms of the volcanic systems delineate the divergent segments of the plate boundary, the Northern, Western, and Eastern Volcanic Zones (NVZ, WVZ, and EVZ), the last two of

which outline the Hreppar Microplate. SVZ marks the Snæfellsnes Volcanic Zone and K, A, B, Kv, G, T, He, Ka, E, V, H, and Kr mark the Krafla, Askja, Bárðarbunga, Kverkfjöll, Grímsvötn, Torfajökull, Hekla, Katla, Eyjafjallajökull, Vestmannaeyjar, Hengill, and Krísuvík volcanic systems. Hveravellir, Laki, and Upptýppingar are shown with Hv, L, and U (Modified from Sólnes et al. (2013) with the help of GBG at IMO)

The boundary is clearly defined by the epicenters of earthquakes that show a narrow zone of deformation (Fig. 1). As it crosses the Iceland platform, however, the deformation zone becomes wider, as shown by the distribution of earthquakes and volcanism in Fig. 2. The boundary breaks up into a series of more or less oblique segments. Sometimes the boundary branches out, and small microplates or blocks are formed that may move independently of the large plates. The largest of these is the Hreppar Microplate that is

bounded by the two subparallel volcanic rift zones in South Iceland (Einarsson 2008; Sigmundsson et al. 1995; La Femina et al. 2005), the Western and Eastern Volcanic Zones (Fig. 2). Each branch or segment of the plate boundary has its own characteristics, both regarding tectonic style and seismicity.

South Iceland Seismic Zone

The southern boundary of the Hreppar Microplate, near 64°N, is a zone of high seismic

Mechanisms of Earthquakes in Iceland, Fig. 3 South Iceland Seismic Zone, epicenters, and suggested source faults of historical earthquakes. Epicenters for the time period 1991–2006 are from the Icelandic Meteorological Office, volcanic systems are from Einarsson and

Sæmundsson (1987), recent fissures and faults are from Einarsson (2010), and source faults of historical earthquakes (1630–1912) are based on fault mapping and investigation of historical documents (Modified from Sólnes et al. (2013) with the help of GBG at IMO)

M

activity, the South Iceland Seismic Zone (SISZ), which takes up most of the transform motion between the Reykjanes Ridge and the Eastern Volcanic Zone (Fig. 3). It has been argued that rifting is dying out in the Western Volcanic Zone and is being taken over by the Eastern Volcanic Zone (Einarsson 2008).

The majority of destructive, historical earthquakes in Iceland have taken place within the South Iceland Seismic Zone. The zone has been defined by destruction areas of historical earthquakes, Holocene surface ruptures, and instrumentally determined epicenters (Figs. 2 and 3). It is oriented E-W and is 10–15 km wide. Destruction areas of individual earthquakes and surface faulting show, however, that each event is associated with faulting on N-S striking planes, perpendicular to the main zone. The overall left-lateral transform motion across the zone thus appears to be accommodated by right-lateral

faulting on many parallel, transverse faults and counterclockwise rotation of the blocks between them, “bookshelf faulting” (Einarsson 1991, 2010).

Earthquakes in South Iceland tend to occur in major sequences in which most of the zone is affected (Einarsson et al. 1981). These sequences tend to last from a few days to about 3 years or even more. Each sequence typically begins with a magnitude 7 event in the eastern part of the zone, followed by smaller events farther west. Sequences of this type occurred in 1896, 1784, 1732–1734, 1630–1633, 1389–1391, 1339, and 1294. The sequences thus occur at intervals that range between 45 and 112 years, and it has been argued that a complete strain release of the whole zone is accomplished in about 140 years (Stefánsson et al. 1993). In addition to the sequences, single events occasionally occur near the ends of the zone, e.g., in 1912 at the eastern end.

The 1896 and 1912 earthquakes were followed by a long quiet interval, which in 1985 led to a long-term forecast of a major earthquake sequence within the next decades (Stefánsson et al. 1993). The forecast was fulfilled in June 2000 when two magnitude 6.5 events occurred in the central part of the zone. The sequence started on June 17 with a magnitude 6.5 event in the eastern part of the zone which was immediately followed by triggered activity along at least a 80 km long stretch of the plate boundary to the west (Árnadóttir et al. 2001, 2004). The second mainshock of about the same magnitude occurred 21 km west of the first one on June 21. It was clearly preceded by clustering of micro-earthquakes near the coming hypocenter (Stefánsson 2011). The mainshocks of the sequence occurred on N-S striking faults, transverse to the zone itself. The sense of faulting was right-lateral strike-slip consistent with the model of bookshelf faulting for the SISZ. The two mainshocks occurred on preexisting faults and were accompanied by surface ruptures expressed by en echelon tension gashes and push-up structures typical for strike-slip faults (Clifton and Einarsson 2005). The main zones of rupture were 15 km long, had a N-S trend, and coincided with the epicentral distributions. Faulting along conjugate faults was also observed, but was less pronounced than the main rupture zones. Faulting extended to a depth of about 10 km as shown by aftershock distribution and modeling of displacement fields at the surface determined by GPS and InSAR measurements (Árnadóttir et al. 2001; Pedersen et al. 2003). The maximum fault displacements according to these models were 2.5 m for both earthquakes.

The observed faulting structures were clearly smaller than those observed in association with earlier historical earthquakes such as those of 1630, 1784, 1896, and 1912. These earlier earthquakes were therefore larger than the earthquakes of June 2000, which is consistent with the measured magnitude of 7 for the 1912 earthquake.

High acceleration was recorded by a network of strong-motion accelerographs. The highest recorded acceleration was 0.83 g, recorded by an instrument in a bridge abutment within 3 km

of the source fault of the June 21 event. Indications of acceleration in excess of 1 g, such as overturned stones, were abundant in the source areas. In light of the high accelerations, the damage to man-made structures was surprisingly low. Only 20 houses were deemed unusable, none of them collapsed, however. Damage was strongly correlated with age of the buildings. There were no casualties and very little injury to humans or animals (Sigbjörnsson and Ólafsson 2004).

The earthquakes of 2000 only released about one fourth of the strain accumulated across the SISZ since the major sequence of 1896–1912. Further activity was therefore anticipated. A strong earthquake occurred near the western end of the zone, in the Ölfus district, on May 29, 2008, between the towns of Selfoss and Hveragerði (Fig. 3). The moment magnitude of the event was about 6.3, but it turned out to be a double event (Decriem et al. 2010; Sigbjörnsson et al. 2009). The first event took place on a fault at the W-foot of Mt. Ingólfssjall. It immediately triggered another slip event on a parallel fault, 4 km to the west. Both sub-events were associated with right-lateral strike-slip on N-S striking faults and had moment magnitudes (M_w) of 5.8 and 5.9, respectively. The surface effects of the earthquakes were locally very strong. High acceleration was seen in the epicentral areas, rock shattering occurred along many topographic protrusions, rockfalls were common on steep slopes, and sandblows were observed in the alluvium of Ölfusá river that crosses the affected area. Damage to houses was widespread even though no house collapsed. Injuries to people were minor.

Combining field knowledge and mapping of surface ruptures, historical documents, and experience from the 2000 and 2008 earthquakes, it is possible to identify with some certainty the source faults of some of the historical earthquakes since 1630 (Fig. 3, Table 1). Magnitudes of events prior to 1912 are estimated by Stefánsson and Halldórsson (1988). It is noteworthy that each earthquake appears to have occurred on separate fault, except possibly those of 1706 and 1896 in the western part of the zone. The repeat time of events on a particular fault therefore is generally longer than 400 years.

Mechanisms of Earthquakes in Iceland, Table 1 Earthquakes in the South Iceland Seismic Zone

Year	Day	Latitude	Longitude	Magnitude	Area
1630	02 21	64.0	−20.21	~7	Land, Minnivellir

Reykjanes Peninsula Oblique Rift

The mid-Atlantic plate boundary goes onshore at the SW tip of the Reykjanes Peninsula and extends from there with a trend of 70° (azimuth) along the whole peninsula (Figs. 2 and 4). The rift zone is highly oblique and is relatively homogeneous until it joins with the Western Volcanic Zone and the South Iceland Seismic Zone at the Hengill triple junction near 64°N and 21.4°W. The most prominent structural elements are extensional, i.e., hyaloclastite ridges (tindar) formed by fissure eruptions beneath the Pleistocene glacier, postglacial eruptive fissures, normal faults, and open fissures. These structures trend mostly highly obliquely to both the plate boundary and the plate velocity vector (Fig. 4). The average trend of several of the most prominent features is 35° (Einarsson 2008). The fissures and normal faults are grouped into swarms, 4–5 of which can be identified and are shown in Fig. 4. Less conspicuous, but probably equally important, are N-S strike-slip faults that cut across the plate boundary at a high angle. They are expressed as N-S trending arrays of left-stepping,

en echelon fissures with push-up hillocks between them. Typical spacing between the faults is 1 km but in some areas it may be as small as 0.4 km. The N-S strike-slip faults may act to accommodate the transcurrent component along the plate boundary in the same way as is explained for the South Iceland Seismic Zone by the bookshelf faulting model.

Seismicity on the Reykjanes Peninsula is high and appears to be episodic in nature with active episodes occurring every 30 years or so. Recent active periods were in the beginning of the 20th century, 1929–1935, 1967–1973, and in 2000. The largest earthquakes in the latest two episodes (1967–1973 and since 2000) are known to have been associated with strike-slip faulting (e.g., Einarsson 1991; Árnadóttir et al. 2004). At the present time, therefore, deformation along the plate boundary appears to be accommodated by strike-slip faulting, possibly with some contribution of crustal stretching. No evidence of magmatic contribution has been detected in the last decades, such as inflation sources, volcanic tremor, or earthquake swarms propagating along

Mechanisms of Earthquakes in Iceland, Fig. 4 Reykjanes Peninsula Oblique Rift, fissure swarms, epicenters of 1997–2006, and identified strike-slip faults shown in blue. Fissure swarms are from Einarsson and Sæmundsson (1987), seismic data are from the Icelandic

Meteorological Office, and the strike-slip faults are based on Clifton and Kattenhorn (2006) to a large extent. The four volcanic systems shown are Reykjanes, Krisuvík, Brennisteinsfjöll, and Hengill (Modified from Sólness et al. (2013) with the help of GBG at IMO)

the fissure swarms. Magmatic activity within this segment also appears to be highly episodic, but with a much longer period, of the order of 1000 years. The latest eruptive period ended in 1240 AD. During this most recent episode, all the volcanic systems of the peninsula were active with several lava eruptions issuing from their fissure swarms (see, e.g., Sólness et al. 2013, pp. 379–401).

Crustal deformation along the plate boundary on the Reykjanes Peninsula appears to occur in two different modes: (1) dry or seismic mode and (2) wet or magmatic mode (Hreinsdóttir et al. 2001). Deformation in the dry mode occurs mostly by strike-slip faulting during periods when magma is not available to the crust in any appreciable quantity. The mode of deformation changes when magma enters the crust. Dikes are opened up against the local minimum

compressive stress, and they propagate into the plates on both sides of the plate boundary and the fissure swarms are activated.

Known significant earthquakes of the Reykjanes Peninsula Oblique Rift are summarized in Table 2. It is noteworthy that following the eruptive period that ended in 1240 AD, no earthquakes are mentioned until 1724. This could be the result of poor documentation, but it is also possible that diking during the magmatic episode left this plate boundary segment completely de-stressed. It then took 500 years of plate movements to build up sufficient stress to produce earthquakes again.

Tjörnes Fracture Zone

The transform motion between the offshore Kolbeinsey Ridge and the Northern Volcanic Rift Zone of Iceland is taken up by the Tjörnes

Fracture Zone, a broad zone of seismicity, strike-slip faulting, and crustal extension (Einarsson 1991; Stefánsson et al. 2008). The zone consists of several subparallel NW-trending seismic zones, termed the Grímsey Oblique Rift, the Húsavík-Flatey Faults, and the Dalvík Seismic Zone (Einarsson 2008), and a few northerly trending rift or graben structures (Fig. 5). Recent GPS measurements indicate that about $\frac{3}{4}$ of the plate transform motion is taken up by the Grímsey Oblique Rift, $\frac{1}{4}$ by the Húsavík-Flatey Faults, and an insignificant part by the Dalvík Zone (Metzger et al. 2013). Yet, all the zones have produced significant and damaging earthquakes in the last 150 years.

The Grímsey Oblique Rift is the northernmost seismic zone and is entirely offshore. It has an overall NW-SE trend but is composed of several volcanic systems with N-S trend. Evidence for Holocene volcanism is abundant on the sea-floor. At its SE end, the zone connects to the Krafla fissure swarm, but the NW end joins the Kolbeinsey Ridge just south of the rapidly disappearing Kolbeinsey Island. The larger earthquakes of the Grímsey Zone seem to be associated with left-lateral strike-slip faulting on NNE-striking faults (Rögnvaldsson et al. 1998). The zone has the characteristics of an oblique rift. There is a striking similarity between the

Reykjanes Peninsula Oblique Rift and the Grímsey Zone. The two zones are symmetrical with respect to the plate separation vector. They are nearly perfect mirror images of each other, with the axis of symmetry parallel to the plate separation vector. The similarity is seen in the overall trend, the en echelon fissure swarms, the transverse bookshelf faults, and the occurrence of geothermal areas. Earthquake swarms are common in both zones.

The second seismic zone, the **Húsavík-Flatey Faults**, is about 40 km south of the Grímsey Zone and is well defined by the seismicity near its western end, where it joins with the Eyjafjarðaráll Rift (E in Fig. 5). This transform zone can be traced on the ocean bottom to the coast in the Húsavík town, continuing on land into the volcanic zone, where it merges into one of its fissure swarms (Fig. 5). This is a highly active seismic zone. The last major earthquakes occurred in 1872 when the town of Húsavík suffered heavy damage during an earthquake sequence, including at least two M 6.5 events. Well-developed faults can be seen along the whole length of this zone. They show evidence of right-lateral faulting and are subparallel to the zone itself. No evidence of bookshelf faulting has been found so far. Volcanism only plays a subordinate role if any, in this zone.

Mechanisms of Earthquakes in Iceland, Fig. 5 Tjörnes Fracture Zone, epicenters 1994–2006, and suggested sources of historical earthquakes since 1755. Fissure swarms are from Einarsson and Sæmundsson (1987), seismic data are from the Icelandic

Meteorological Office, and the sources of the historical events are from Stefánsson et al. (2008). E marks the Eyjafjarðaráll Graben and P the Peistareykir volcanic system (Modified from Sólnes et al. (2013) with the help of GBG at IMO)

A third zone, the **Dalvík Zone**, is indicated by scattered seismicity about 30 km south of the Húsavík-Flatey Faults (Fig. 5). Earthquakes as large as M_s 7 have occurred in this zone, but it lacks clear topographic expression. In spite of rather clear alignment of epicenters, the Dalvík Zone is not seen as a throughgoing fault on the surface. A common feature of all three seismic zones is the occurrence of earthquakes on transverse structures, similar to that observed in the South Iceland Seismic Zone and the Reykjanes

Peninsula. This is clearly seen in the Dalvík Zone (Fig. 5). In spite of apparently slow strain accumulation in this zone, it has produced two significant earthquakes in the last century, the Dalvík earthquake of 1934 (M 6.3) that caused considerable damage in the town of Dalvík and the 1963 Skagafjörður earthquake (M 7.0) offshore in the mouth of Skagafjörður, one of the largest earthquakes in Iceland in the last century.

Large earthquakes of the Tjörnes Fracture Zone during the last centuries are summarized

Mechanisms of Earthquakes in Iceland, Table 3 Earthquakes in the Tjörnes Fracture Zone

Year	Day	Latitude	Longitude	Magnitude	Area
1755	09 11	66.13	–17.76	~7	Húsavík-Flatey
1838	06 12	66.12	–18.82	6.5	Fljót, Dalvík Zone
1872	04 18	66.08	–17.45	6.5	Húsavík
1872	04 18	66.18	–18.04	6.5	Flatey

1910	01 22	66.35	–17.94	7.0	Grímsey
1921	08 23	67	–18	6.3	
1934	06 02	66.00	–18.44	6.2	Dalvík
1963	03 27	66.23	–19.60	7.0 M _S	Skagafjörður, Dalvík Zone
1976	01 13	66.23	–16.50	6.4 M _S	Kópasker, Grímsey Oblique Rift

in Table 3, based mainly on Stefánsson et al. (2008). For the pre-instrumental era, i.e., prior to 1960, the location of the epicenters is uncertain. Most of the zone is offshore and the felt areas are therefore poorly constrained. In addition, some of the events may belong to a series of triggered events, similar to recent events in South Iceland. The felt reports may therefore belong to different events within the sequence that will further confuse the issue. In addition to the large historical earthquakes in Table 3, several sequences and swarms containing events as large as magnitude 5.6 have occurred in recent decades, along the GOR in 1967–1969 and 2013, and in Eyjafjarðaráll-HFF in 2012.

The focal mechanisms have only been instrumentally determined for the 1963 and 1976 events. Both are strike-slip mechanisms on ESE-striking (right-lateral) or NNE-striking (left-lateral) fault planes. The aftershock distributions (see Fig. 5) would favor the ESE plane as the fault plane for the 1976 event, but the NNE plane for the 1963 event. It may be inferred that the other earthquakes are also caused by strike-slip faulting, except possibly the 1885 earthquake. It occurred within the fissure swarm of the Peistareykir volcanic system and may have been related to rifting activity. From the distribution of background seismicity, it may be inferred that the 1755 and 1872 earthquakes took place on the main Húsavík-Flatey Faults, whereas the 1838, 1910, 1934, and 1963 earthquakes occurred on bookshelf-type faults, transverse to the seismic zones.

Volcanic Zones

Earthquakes occur in the volcanic zones of Iceland but are rarely large (e.g., Pedersen et al. 2007). Events larger than magnitude 5 are only known in connection with unusually large events such as during the Krafla rifting episode in 1975–1984 and at Bárðarbunga volcano prior to the Gjálp eruption of 1996. Events of magnitude 6 and larger have so far not been recorded. It should be noted, however, that large earthquakes have sometimes occurred in the transform zones of South and North Iceland following or in connection with major rifting events in the adjacent divergent parts of the plate boundary. The best documented case is the Kópasker earthquake of TFZ in 1976 during the first rifting event of Krafla (Einarsson 1991). Other cases are the SISZ earthquakes of 1784 following the Laki eruption of 1783, the 1872 earthquakes of the Húsavík-Flatey Faults in connection with an eruption 1867 offshore and the Askja rifting episode of 1874–1875, and the SISZ earthquakes of 1732–1734 following an unusually active period in the rift zones.

Inspection of Fig. 2 reveals a low-magnitude background seismicity of several of the central volcanoes. Apparent spatial correlation with high-temperature geothermal areas suggests that this activity is the expression of heat mining of magmatic sources within these volcanoes. The cooling of hot rock bodies leads to contraction, stress changes, and fracturing. The resulting earthquakes are expected to have a large non-double-couple component in their source mechanism, which has been confirmed in the

case of the Hengill and Krafla volcanoes (Miller et al. 1998). Other low-level seismicity sources that may have similar origin include Peistareykir, Askja (SE caldera part), Kverkfjöll, Grímsvötn, Hveravellir, Torfajökull, Katla (caldera part), Krísuvík, and Reykjanes.

Some of the volcanoes have been shown to go through inflation-deflation cycles during limited times, i.e., a magma chamber is inflated by inflowing magma and subsequently deflates, either by eruption to the surface or by intrusion of a dike. The best documented case is that of Krafla during the rifting episode of 1975–1984, but also Grímsvötn has shown this behavior since 1997 and Hekla during the last decades (Sturkell et al. 2006). Inflation and deflation of a magma chamber leads to stress changes in the chamber roof and eventually to earthquakes if the stress change is large enough. Krafla and Grímsvötn have shown seismicity that conforms with this mechanism, but the Hekla chamber is deep-seated. It is apparently below the brittle-ductile transition and has not produced stress changes large enough to cause brittle failure during recent cycles. The largest earthquakes of this origin have reached magnitude 5, during deflation of Krafla in 1976 (Einarsson 1991).

The brittle-ductile transition is shown to be at about 8–9 km depth at the constructive plate boundaries in Iceland but becomes deeper with increasing age (e.g., Stefánsson et al. 1993). Occasionally earthquakes have been detected at considerably larger depth in the volcanic zones, indicating brittle failure of crustal material that would be ductile at normal strain rates, i.e., strain rates in the crust associated with plate movements. In the case of the 1973 Heimaey (Vestmannaeyjar) and the 2010 Eyjafjallajökull eruptions, these “deep” events occurred in connection with obvious magmatic movements and high strain rates. In other cases the magmatic connection is inferred, mainly because high strain rate is the only known mechanism to cause brittle failure at abnormal depth. A dike intrusion at 15–30 km depth at Upptyppingar in the Northern Volcanic Zone in 2007–2008 was accompanied by an earthquake swarm and verified by surface deformation measurements (e.g., Hooper

et al. 2011). Persistent deep earthquake activity in the Askja volcano area at depths of 15–34 km has been interpreted as the expression of magma movements in the lower crust (Soosalu et al. 2009), similarly deep events in the Katla area (Jakobsdóttir 2008).

A large sequence of magmatic rifting events occurred in the Northern Volcanic Zone, beginning in 1974 and lasting until 1989, with diking and eruptions in the interval 1975–1984. The activity was mainly concentrated on the Krafla volcanic system but also extended into the adjacent Grímsey Oblique Rift, a part of the Tjörnes Fracture Zone. Most of this time, magma apparently ascended from depth and accumulated in a magma chamber at about 3 km depth beneath the Krafla volcano. The inflation periods were punctuated by sudden deflation events lasting from several hours to 3 months when the walls of the chamber were breached and magma was injected into the adjacent fissure swarm accompanied by propagating earthquake swarms (Wright et al. 2012). Twenty deflation events were documented. Large-scale rifting was observed in the fissure swarm during these deflation events, and in nine of them, magma reached the surface in basaltic fissure eruptions lasting from a half hour to 14 days. The earthquakes accompanying the diking were smaller than magnitude 4.5, except the triggered events in the adjacent Tjörnes Fracture Zone (Einarsson 1986, 1991).

A unique earthquake sequence occurred at the Bárðarbunga volcano in Central Iceland during the period 1974–1996. Fifteen earthquakes of magnitude 5 and larger occurred in the caldera region at fairly regular intervals during this period. The focal mechanisms were characterized by reverse faulting but with a significant non-double-couple component (Einarsson 1991; Ekström 1994). Each one of the large events was preceded by a few months of increasing seismic activity, but followed by quiescence or only very few earthquakes. This behavior is highly anomalous. Most other large earthquakes are followed by months or years of high aftershock activity that gradually decays with time. The last large event of the sequence occurred on September

29, 1996 ($M_w = 5.6$). In contrast to previous events, it was immediately followed by an intense earthquake swarm in the summit region of Bárðarbunga. The earthquakes migrated to the SE and S, and in the evening of September 30, they were replaced on the seismic records by continuous volcanic tremor signifying the beginning of an eruption. The eruption is termed the Gjálp eruption and was one of the larger eruptions of the twentieth century in Iceland (Einarsson et al. 1997; Guðmundsson et al. 1997). It occurred on a 7 km long fissure SE of the caldera and beneath the Vatnajökull glacier. It resulted in a catastrophic flood of about 4 km³ of meltwater.

Several interpretations of the cause of the Bárðarbunga earthquakes have been proposed. The one favored here assumes that they are the result of pressure drop in a magma chamber beneath the caldera of Bárðarbunga (Einarsson 1991). This drop began prior to 1974 and continued until the plumbing of the volcano changed in 1996. The earthquakes were, according to this interpretation, generated by piecemeal collapse of the caldera, by reverse faulting along the curved caldera main fault. The curvature produced the non-double-couple component of the focal mechanism. In the final event in 1996, a pocket of magma was cut by the fault, leading to the formation of a ring dike and triggering a dike propagating out of the caldera to feed the Gjálp eruption.

Intraplate Earthquakes

Even though earthquakes are rare outside the plate boundary areas of Iceland, the class of intraplate earthquakes is of considerable importance for the assessment of seismic risk. The main reason is that the population of Iceland is highly clustered, with half the population concentrated in the Reykjavík metropolitan area, 10–30 km off the plate boundary. Estimating correctly the probability of a large earthquake within the city is a fundamental issue.

Considering Fig. 2 and an earlier analysis of intraplate earthquakes in Iceland (Einarsson 1989), three classes of intraplate earthquakes can be identified:

1. *Earthquakes in West Iceland.* Earthquakes occur west of the main rift zone through Iceland, within the tongue of lithosphere that is bounded by the two transform zones in North and South Iceland. This seismicity is associated with internal deformation of the North American Plate. Best known are the Borgarfjörður events of 1974 in Central West Iceland (Fig. 2), an extended sequence that culminated with an earthquake of m_b 5.5. They were associated with normal faulting on NE- or E-striking faults. Crustal extension in this area may be linked with the center of the Iceland hotspot and its track into the North America Plate. The Snæfellsnes Volcanic Zone may be another expression of this extension (Fig. 2). It is a zone of recent volcanic activity laying unconformably on basalts of 6 Ma age. Distributed, low-level seismicity is seen in Fig. 2 connecting the Snæfellsnes Volcanic Zone to the Western Volcanic Zone.
2. *Earthquakes at the insular shelf edge off Eastern and SE Iceland.* Iceland sits on a platform bounded by a relatively sharp edge that resembles a continental shelf edge (see Fig. 1). It is particularly sharp off the E and SE coast, and there it is seismically active. The edge in this area represents a discontinuity in crustal and mantle structure related to eastward jumps in the plate boundary. There is probably an age jump of 15–25 m.y. and a resulting thermal discontinuity across the shelf edge. The present seismicity is thus interpreted as the result of differential lithospheric response to loading or different cooling rate on either side of the edge.
3. *Earthquakes under and around the Vatnajökull glacier.* Small earthquakes are occasionally seen in the area of Vatnajökull glacier, the largest ice mass of Iceland. The ice is shrinking due to the global warming of the climate. This leads to crustal uplift to restore isostatic equilibrium. The area around the glacier has been shown to rise 10–25 mm/year in recent years (Árnadóttir et al. 2009), and it is a probable cause of this low-level seismic activity.

Summary

Most earthquakes in Iceland are causally linked with the mid-Atlantic plate boundary that crosses the country. The largest earthquakes occur in the two major transform zones, one in South Iceland and the other in North Iceland, that link the subaerial volcanic rift zones with the spreading ridge segments offshore. These earthquakes are caused by strike-slip faulting and may reach magnitude of 7. The transform zones are rather complicated structures, and in many cases the faulting takes place on several parallel strike-slip faults that strike almost perpendicularly to the plate boundary, a faulting mode termed “bookshelf faulting.” Triggering of earthquakes has been observed, both by other earthquakes and by rifting in an adjacent zone. Earthquakes in the volcanic and divergent zones of Iceland are generally much smaller. Events of magnitude 5–6 have been found to occur within volcanic calderas. In the case of Krafla in 1975–1976, they were associated with deflation of the volcano’s magma chamber. Deflation is also suspected to be the cause of a persistent series of events in the Bárðarbunga caldera in 1974–1996. The focal mechanisms were of the reverse faulting type with a significant non-double-couple component. Dike intrusions and other magmatic processes are responsible for some earthquake activity, mostly at lower magnitudes still. Intraplate earthquakes have been documented in several cases. In West Iceland normal faulting was found to be responsible for a sequence of events in 1974, culminating in an earthquake of magnitude 5.5. The shelf edge off the SE, E, and NE coast is found to be seismically active, and the present isostatic uplift around the shrinking Icelandic glaciers is probably responsible for occasional events there.

Mechanisms of Earthquakes in Vrancea

Mircea Radulian

National Institute for Earth Physics, Măgurele, Romania

Synonyms

Earthquake; Focal mechanism; Vrancea

Introduction

The Vrancea seismic region is defined as an earthquake nest, meaning a particular kind of intermediate-depth earthquake concentration or clustering. First, an earthquake nest implies a volume of intense activity that is isolated from nearby activity. Second, this activity is persistent over time (at least for decades). From this point of view, nests are distinct from aftershock sequences or earthquake swarms. The definition of what represents an earthquake nest is somewhat arbitrary, and there are many regions in the world where clustering of seismic activity can be categorized as earthquake nests. Nevertheless, earthquake nests are associated to three most famous and intensively studied areas, Bucaramanga (Colombia), Hindu Kush (Afghanistan), and Vrancea (Romania).

Earthquake nests provide perhaps the best setting for understanding the physical mechanism responsible for intermediate-depth earthquakes (waveform data related to a well-defined seismogenic zone are practically available continuously). Mechanisms involving dehydration embrittlement or thermal shear runaway are mostly invoked to explain brittle or brittle-like failure at intermediate depths.

The Vrancea nest occurred in the last stage of the Carpathians tectonic history. Formation of Carpathians comprises first an extension phase between the European and Apulian Plates in Triassic to Early Cretaceous, then a continental collision phase of the European Eurasian and African Plates and finally a post-collision phase (11–0 Ma), when a set of mechanisms were developed such as slab detachment, oceanic or continental lithosphere delamination, thermal or lithospheric instabilities, or combination of them. The collision led to the closure of the Alpine Tethys and to the lateral extrusion of Intra-Alpine plate. The extrusion led to a fan-shaped migration of the Carpathian collision front, accommodated by subduction of the last remnant of the Tethys Ocean. The Vrancea, located at the southeastern bending of Carpathians, represents the only segment of the mountain belt where significant seismicity is recorded at present, concentrated in a

finger-shaped pattern descending almost vertically in the mantle.

Several geodynamic models have been proposed to explain the nature of the seismogenic body beneath the Vrancea region (Ismail-Zadeh et al. 2012). Basically, they belong to two categories: (1) a relic oceanic lithosphere, either attached or already detached from the continental crust, and (2) continental lithosphere that has been delaminated, after continental collision and orogenic thickening. There are arguments in favor and against these two types of models. Oceanic-type models involve break-off process (Fuchs et al. 1979; Wortel and Spakman 2000; Sperner et al. 2001), lateral migration of an oceanic slab (Girbacea and Frisch 1998; Gvirtzman 2002), or subduction and lateral tearing of a slab (Martin and Rietbrock 2006; Wenzel et al. 1998; Wortel and Spakman 2000). Continental-type models involve active delamination (Knapp et al. 2005; Koulakov et al. 2010) or gravitational instability (Lorinczi and Houseman 2009; Ren et al. 2012). The recent results of Bokelman et al. (2014) regarding the dispersion of P waves and the hypothesis of a “double seismic zone” (Bonjer et al. 2005; Radulian et al. 2007; Cărbunar and Radulian 2011) bring evidence in favor of an oceanic nature of the subducting lithosphere.

Tectonic Setting

The earthquake-prone Vrancea region is situated at the bend of the Southeast Carpathians at the contact of East European Platform (EEP) to the north and northeast, Scythian platform to the east, North Dobrogea orogeny to the southeast, Moesian Platform to the south and southwest, and Carpathian orogen and Transylvanian basin (Intra-Alpine plate) to the west and northwest (Fig. 1).

The region is characterized by the frequent occurrence of strong intermediate-depth earthquakes ($M \sim 7$), confined in a narrow zone ($\sim 60 \times 20 \text{ km}^2$ on a horizontal section) within a cold vertically descending lithosphere. The part of the descending lithosphere which is

Mechanisms of Earthquakes in Vrancea, Fig. 1 Location of the Vrancea region. The North Dobrogea zone is located between the Scythian and Moesian Platforms, bounded by Trotuș and Peceneaga-Camena Faults

seismically active is confined in the depths between 70 and 170 km, with no seismicity practically detected below this range. This volume fits well within a high seismic wave velocity body, evidenced by all tomographic studies (e.g., Oncescu 1984; Koch 1985; Wortel and Spakman 2000; Sperner et al. 2001; Martin and Rietbrock 2006; Koulakov et al. 2010). The mantle seismogenic volume is separated from the sub-Carpathian crust by a relatively aseismic zone between 40 and 70 km depth.

The seismicity in the Vrancea overlying crust, spread mostly to the southeast between Trotuș and Intra-Moesian faults, is significantly less important as magnitude (below 5.5) and energy release rate (about four orders of magnitude smaller than in the mantle; Ismail-Zadeh et al. 2012). There was debate on a possible causative relation between mantle and shallow

events, as was suggested by the simple geometry of seismicity alignments (Răileanu et al. 2009; Bonjer et al. 2008; Cărbunar and Radulian 2011). Mitrofan et al. (2014) showed that the triggering effect of the Vrancea intermediate-depth events upon the shallow events in different segments of the Carpathians foredeep region is not noticeable, except one lineament located to the east, close to Danube River, in the Mărăști-Galați-Brăila area. They explain this triggering mechanism by a process of exhumation of the material originating in a slab slicing progression that is consistent with the reverse-faulting mechanism predominating in the Vrancea intermediate-depth domain (see text below).

The intermediate-depth earthquakes along Vrancea strongly affect extended areas in the Southeast and Central Europe. For this reason, the Vrancea source is controlling seismic hazard

level in almost half of the territory of Romania and in cross-border areas as well (in Bulgaria, Republic of Moldova, Serbia, Ukraine). At the same time, the particular pattern of the macroseismic effects provides an efficient clue to identify a major earthquake that occurred in the Vrancea zone in historical times (24 events with $M_w > 7$ since 1,000 according to SHEEC catalogue; Stucchi et al. 2013). The four large events recorded during the last century (10 November 1940, 4 March 1977, 30 August 1986, 30 May 1990) had a significant impact on a large geographical area (Kronrod et al. 2013). The event of 4 March 1977 was the most disastrous, especially toward SW of the epicenter: 1,570 people died, 11,300 were injured, and 32,500 residential and 763 industrial units were destroyed or were seriously damaged in Romania (Sandi 2001).

Analysis of the macroseismic and instrumental data from the intermediate-depth Vrancea earthquakes revealed several peculiarities of the earthquake effects (e.g., Mândrescu and Radulian 1999; Ismail-Zadeh et al. 2012; Kronrod et al. 2013) that can be summarized as follows:

- Extended areas, N-W elongated, are strongly affected.
- NE-SW enhancement of effects coincides with the geometry of seismicity and of the fault-plane solutions.
- Source directivity caused by particular rupture orientation can play a significant role in distributing asymmetrically the intensity effects at regional scale.
- Local and regional geological conditions can control the amplitudes of earthquake ground motion to a larger degree than magnitude or distance.
- Apparently the focal depth can shape to some extent specific patterns in the ground motion distribution.

Focal Mechanisms in the Vrancea Source

All the previous studies on the subcrustal seismic activity in the Vrancea region outline a predominant dip-slip, reverse faulting, characterizing

both the moderate and strong earthquakes (Enescu 1980; Oncescu 1987; Oncescu and Trifu 1987). In most of the cases, the principal T axis tends to be vertical, the principal P axis tends to be horizontal and oriented perpendicular to the Carpathians arc, and one nodal plane is dipping about 70° toward NW, while the other nodal plane is dipping SE.

The focal mechanisms of the largest Vrancea earthquakes that occurred since 1977 up to the present ($M_w \geq 5.0$) from the CMT catalogue (Dziewonski et al. 1981; <http://www.globalcmt.org/>, accessed on February 2014), represented in Figs. 2 and 3, indicate reverse faulting, and in a number of cases, the focal mechanisms are connected with a strong strike-slip component. The parameters of the nodal planes and P and T principal axes are given in Table 1. These mechanisms are connected with the sinking of the lithosphere in the mantle beneath the Vrancea region. The rate of seismic moment per volume, $\sim 0.8 \times 10^{19}$ Nm/year, in Vrancea is comparable to southern California (Wenzel et al. 1998) since the seismic active volume is extremely concentrated in space.

The fault-plane solutions of the instrumentally recorded large earthquakes are remarkably similar (Fig. 4). The individual solutions for the strong earthquakes of 10 November 1940 ($M_w = 7.7$), 4 March 1977 ($M_w = 7.4$), 30 August 1986 ($M_w = 7.1$), and 30 May 1990 ($M_w = 6.9$) show one another only slight variations. These results suggest that the large earthquakes in the Vrancea subcrustal region are governed by the same geodynamic process.

The nodal plane typically striking NE-SW ($\sim 220^\circ$) and dipping 60 – 70° to the NW is ascribed to be the rupture plane (Oncescu and Bonjer 1997; Sperner et al. 2001; Wenzel et al. 2002). This plane coincides with the location of the aftershocks of the major events (Fuchs et al. 1979; Oncescu and Trifu 1987; Trifu et al. 1992). For some of the moderate-size events ($M_w < 7$), the rupture plane is rotated about 90° and dips to the SE (events of 02 October 1978 M_w 5.2, 31 May 1990 M_w 6.4, 28 April 1999 M_w 5.3, and 18 June 2005 M_w 5.2 in Fig. 2). In all cases, the rake angle is close to 90° (i.e., up dip).

Mechanisms of Earthquakes in Vrancea, Fig. 4 Fault-plane solutions for the major Vrancea earthquakes instrumentally recorded (equal-area lower-hemisphere projection)

Reverse faulting with down-dip extension is predominant along the entire depth range of the seismogenic volume except some variations noticed around 100 km depth (Oncescu and Trifu 1987; Oncescu and Bonjer 1997; Radulian et al. 2002).

The projection of the earthquake foci on a vertical plane crossing the Vrancea area perpendicularly to the Carpathians bend (projection C-D in Fig. 2) suggests the presence of a double seismic zone (Bonjer et al. 2008; Cărbunar and Radulian 2011), which is a characteristic of many subduction zones. Only that in this case the shift between the two nearly parallel “layers” is of the order of location errors (10 km). According to the earthquake triggering scenario suggested by Ganas et al. (2010), there are two NW-dipping nearly parallel planes responsible for triggering successive major events. They are optimally oriented planes of weakness inside the slab to drive the release of the accumulated strain. The foci of the large Vrancea shocks instrumentally recorded are clustered on these two faults accommodating the deformation of the slab (down-dip extension) by shear failure. One cluster is located around 90–100 km depth and the other around 130–140 km depth. A third,

subparallel, major, NW-dipping plane of weakness at depth of about 150–160 km cannot be excluded if the hypothesis of seismic gap at this depth range (Oncescu and Bonjer 1997 and Hurukawa et al. 2008) is valid.

Summary

The Vrancea seismic region is a particularly active source in Europe, embedded in the mantle beneath the Southeastern Carpathians arc bend in a continental tectonic setting. Despite the extreme concentration of the focal volume, frequent earthquakes of magnitude above 7 are generated here in an isolated high-velocity lithospheric body. The focal mechanisms show predominant reverse faulting with the T axis along down dip. The distribution of the strong ground motion is characterized by specific asymmetric patterns, affecting extended areas elongated along NE-SW direction. The elongation coincides with the pattern of the seismicity and the geometry of the rupture plane dipping toward NW. Recent higher-resolution investigations reveal the existence of possible parallel alignments of weakness crossing the seismogenic volume along planes oriented NE-SW and dipping nearly vertically toward NW. These weakness planes are developed separately in two or eventually three segments on depth (centered at 90–100, 130–140, and 150–160 km depth, respectively) where the seismicity is clustered and major shocks nucleate alternatively in time. Repeated generation of large events along parallel sub-faults separated in depth suggests a combination of dehydration process that preferentially weakens preexisting sub-faults in the subducting crust (Kiser et al. 2011) and thermal shear runaway process (Wiens and Sniders 2001).

Accelerometer; Displacement sensor; MEMS (microelectromechanical systems); Restoring force characteristics; SDOF (single degree of freedom) mass-spring system; Sensor network; Velocimeter

Introduction

MEMS is an abbreviation for microelectromechanical systems. MEMS sensor is a measurement device consisting of mechanical parts for picking up events or environmental changes (i.e., sensors) and electric circuit for amplifying and filtering the signals from sensors. MEMS sensor is usually integrated on a small circuit board.

The major advantages of MEMS sensors for measurement of structure seismic response are their small size, low power consumption, and low price in contrast with their high accuracy in measurement. For example, a typical price of MEMS accelerometers is less than 10 USD. In spite of this low cost, a MEMS accelerometer with 3 axes, ± 2 g full scale, 5 mm $\times$ 5 mm $\times$ 2 mm size, 1.1 mA current consumption at the input voltage of 2.7 V, and noise density of 175 $\mu\text{g}/\sqrt{\text{Hz}}$ is available off the shelf.

MEMS sensors are basically implemented as fine patterns printed on silicon wafers. These patterns are the combination of the mechanical parts corresponding to the sensor pickup and the electric circuit to convert, amplify, and filter the signal from sensor pickup. The size and the energy consumption of the MEMS can be suppressed by implementing the patterns on the silicon wafers as small as possible. The micro-fabrication technology made mass production and distribution of low-cost MEMS sensors possible.

A typical micro-fabrication process of the MEMS sensors is a photolithograph method. In photolithography, photosensitive material is painted on a silicon wafer. Then, this layer is masked by the patterns of the electric circuit. After the exposure of this wafer to the light, unmasked area is scraped off by reactive gas or fluid (gas, dry etching; fluid, wet etching). Finally, the masked area remains as fine patterns of the electric circuit. This photolithographic method enables us to automatically produce more than 1,000 circuit boards (each of them corresponds to a MEMS sensor) from one silicon wafer plate (30 cm in diameter). This is the key production technology for low-cost MEMS sensors.

Among many types of MEMS sensors, MEMS accelerometers are mainly used in the field of earthquake engineering. The measurement principle of most MEMS accelerometers is that of SDOF (single degree of freedom) mass-spring system. If some condition (mentioned below in this manuscript) is satisfied, the relative displacement between the mass and the support is proportional to the absolute acceleration of the support.

This is the overview of the MEMS technology and the MEMS sensors related to the field of earthquake engineering. This manuscript is organized as follows. First, the difference between a displacement sensor, a velocimeter, and an accelerometer is illustrated by the analysis of SDOF mass-spring system. Through this analysis, the reason for (i) many MEMS accelerometers are available with low cost, and (ii) no MEMS velocimeters and MEMS displacement sensors are available. Also, the limitation of the MEMS accelerometers and the point to be noted for usage of the MEMS accelerometers are discussed. This discussion leads us to a possible application of the MEMS accelerometers in the field of earthquake engineering.

Vibration Measurement Device

Consider an SDOF (single degree of freedom) mass-spring system shown in Fig. 1. The mass is m , spring constant is k , and the dashpot is c . The governing equation of this system is

$$m(\ddot{y}(t) + \ddot{z}(t)) + c\dot{z}(t) + kz(t) = 0 \quad (1)$$

where t is time. Suppose that the displacement of the support is $y(t) = Y_0 \sin \omega t$. Then Eq. 1 becomes

$$\ddot{z}(t) + 2\zeta\omega_0\dot{z}(t) + \omega_0^2 z(t) = \omega^2 Y_0 \sin \omega t \quad (2)$$

where $\omega_0^2 = k/m$ and $\zeta = c/\sqrt{4mk}$. The following expression for $z(t)$ can be obtained by solving Eq. 2.

$x(t)$: absolute displacement of the mass
 $y(t)$: absolute displacement of the support
 $z(t)$: relative displacement of the mass to the support

MEMS Sensors for Measurement of Structure Seismic Response and Their Application, Fig. 1 SDOF mass-spring system (simplified model for vibration measurement device)

$$z(t) = \frac{(\omega/\omega_0)^2}{\sqrt{[1 - (\omega/\omega_0)^2]^2 + (2\xi\omega/\omega_0)^2}} Y_0 \sin(\omega t - \phi),$$

$$\phi = \tan^{-1} \left(\frac{2\xi\omega/\omega_0}{1 - (\omega/\omega_0)^2} \right) \quad (3)$$

Consider the following three cases for the angular frequency of the absolute displacement of the support ω and the natural angular frequency of the mass-spring system ω_0 :

Case 1: $\omega_0 \ll \omega$

Case 2: $\omega_0 \cong \omega$

Case 3: $\omega_0 \gg \omega$

In Case 1, since $[1 - (\omega/\omega_0)^2]^2 \cong (\omega/\omega_0)^4 \gg (2\xi\omega/\omega_0)^2$ and $\phi = \pi$,

$$z(t) \cong -Y_0 \sin \omega t = -y(t). \quad (4)$$

Equation 4 means that for $\omega_0 \ll \omega$, the absolute displacement of the support $y(t)$ is almost equal to $-z(t)$, where $z(t)$, the relative displacement of the mass to the support, is the measurable quantity. Therefore, for the case of $\omega_0 \ll \omega$, this SDOF mass-spring system can be used as a displacement sensor by converting the relative displacement between the mass and the support to some electric signal.

In Case 2, $\omega_0 \cong \omega$ and $\phi = \pi/2$ result in

$$z(t) \cong \frac{1}{2\xi\omega_0} Y_0 \cos \omega t = \frac{1}{2\xi\omega_0} \dot{y}(t). \quad (5)$$

Equation 5 means that for $\omega_0 \cong \omega$, the relative displacement of the mass to the support, $z(t)$, is almost proportional to the absolute velocity of the support, $\dot{y}(t)$. Therefore, when the condition for Case 2 is satisfied, this SDOF mass-spring system can be used as a velocimeter by converting the relative displacement between the mass and the support to some electric signal.

In Case 3, since $\omega_0 \gg \omega$, $\omega/\omega_0 \cong 0$ and $\phi = 0$. Therefore,

$$z(t) \cong \frac{1}{\omega_0^2} \omega^2 Y_0 \sin \omega t = -\frac{1}{\omega_0^2} \ddot{y}(t). \quad (6)$$

Equation 6 means that in Case 3, the relative displacement of the mass to the support, $z(t)$, is almost proportional to the absolute acceleration of the support, $\ddot{y}(t)$. Therefore, for the case of $\omega_0 \gg \omega$, this SDOF mass-spring system can be used as an accelerometer by converting the relative displacement between the mass and the support to some electric signal.

Here, the physical meaning of each case for the SDOF mass-spring system shown in Fig. 1 should be discussed. In Case 1, this SDOF mass-spring system works as a displacement sensor. The condition $\omega_0 \ll \omega$ requires relatively small ω_0 . Since $\omega_0 = \sqrt{k/m}$, small ω_0 means large m and small k . Thus, an SDOF displacement sensor consists of a very heavy mass supported by an extremely soft spring which results in a bulky and fragile device. This is the reason for nonexistence of a MEMS displacement meter based on the SDOF mass-spring system.

In Case 2, $\omega_0 \cong \omega$ requires a subtle tuning of the device. Thus, a velocimeter becomes a precision instrument and this is not suitable for the mass production on a silicon wafer (typical production method for MEMS devices). This is why there exists no MEMS velocimeter based on the SDOF mass-spring system. One comment should be added for an SDOF velocimeter. As shown in Eq. 5, the proportional constant between the absolute velocity of the support $\dot{y}(t)$ and the measured relative displacement of the mass $z(t)$ is $1/(2\xi\omega_0)$. Ordinary materials have small ξ in the order of 0.05. Therefore, $\dot{y}(t)$ is amplified a lot. The gain of the SDOF velocimeter is large enough for using this as a precise seismometer.

In Case 3, $\omega_0 \gg \omega$ means relatively large ω_0 . Since $\omega_0 = \sqrt{k/m}$, large ω_0 means small m and large k . Thus, an SDOF accelerometer consists of a light mass supported by an extremely hard spring which results in a small and tough device. The smaller and the tougher, the device works as a better accelerometer. This nature of the SDOF accelerometer is suitable for the mass production on a silicon wafer. This is why MEMS accelerometers with reasonable cost are widely supplied in the market.

There is an additional explanation for MEMS accelerometers. As shown in Eq. 6, the proportional constant between the absolute acceleration of the support $\ddot{y}(t)$ and the measured relative displacement of the mass $z(t)$ is $-1/\omega_0^2$. Since large ω_0 is the requirement for an SDOF accelerometer, the amplification factor $1/\omega_0^2$ becomes very small. Therefore, a MEMS accelerometer should have an internal electric circuit for amplifying the signal. The measuring accuracy of the MEMS accelerometer is limited by this amplifier circuit. The accuracy of this amplifier circuit is the noise density mentioned at the beginning of this manuscript. The lowest noise density of currently available MEMS accelerometers is in the order of several tens of $\mu g/\sqrt{\text{Hz}}$. Thus, acceleration measurement using a MEMS accelerometer with the bandwidth of 100 Hz results in the noise in the order of 1 gal. Compared with non-MEMS precise accelerometers whose measurement noise is in the order of a few milligal, the measurement accuracy of the MEMS accelerometer is not high. This implies limitation of the application of the MEMS accelerometer in the field of earthquake engineering.

Application of MEMS Accelerometers for Earthquake Engineering

Sensor network has been started by Smart Dust project (Kahn et al. 1999) in the late 1990s. Ever since, sensor network technology has been rapidly advanced. This is mainly because of the

advancement of MEMS technology. This sensor network technology has been also imported to the field of earthquake engineering. Measurements of the ambient vibration of the structures and the structure seismic response to weak ground motion are performed by using MEMS accelerometer sensor network. These measurements are intended for structural health monitoring. However, no successful example has been observed in these structural health monitoring applications by densely deployed MEMS accelerometers (Farrar et al. 2001; Farrar and Worden 2007). The major reason for these unsuccessful attempts for MEMS accelerometer-based structural health monitoring is the insufficient accuracy of MEMS accelerometers. Structural health monitoring using the ambient vibration of the structures and the structure seismic response to weak ground motion requires the change in the structural response to weak input (less than 10 gal). Therefore, the accuracy of MEMS accelerometers mentioned before (1 gal for 100 Hz measurement bandwidth) is obviously insufficient. MEMS accelerometer-based application for earthquake engineering has to be the measurement of structure seismic response to strong (at least 100 gal) ground motion.

An example application of a sensor network system equipped with MEMS accelerometers is the measurement of restoring force characteristics of structures subjected to strong ground motion. Right after a severe earthquake, the damage level of the structures in disaster-stricken region has to be quickly identified. For this

purpose, MEMS accelerometer sensor network system can be used.

Structures of a simple shape such as the standard viaducts for railways and highways can be safely approximated as an SDOF mass-spring system as shown in Fig. 2. Then, the acceleration at the top of the structure is proportional to the inertia force acting on the mass and the relative displacement between the top and the bottom of the structure corresponds to the relative displacement between the mass and the support. Therefore, if the acceleration at the top of the structure and the relative displacement between the top and the bottom of the structure subjected to ground motion can be observed, the property of the spring, i.e., the restoring force characteristics of the structure, can be obtained.

At the top and the bottom of the structure shown in Fig. 2, sensor nodes equipped with a MEMS accelerometer are installed. These sensor nodes are also equipped with wireless communication device and a synchronized measurement can be performed between these sensor nodes (Ikeda et al. 2012).

Typical restoring force characteristics are shown in Figs. 3 and 4. The vertical axis is the acceleration at the top of the structure and the horizontal axis is the relative displacement between the top and the bottom of the structure. Subjected to weak ground motion shown in Fig. 3, the structure remains elastic and the restoring force characteristics are linear. On the other hand, Figure 4 corresponding to the case of strong ground motion shows

hysteresis curves which indicate the plastic response of the structure.

These restoring force characteristic can be obtained by a synchronized acceleration measurement using a pair of sensor nodes installed at the top and the bottom of the structure. The relative displacement can be obtained through time integration of the acceleration data using a band-pass filter which includes the lowest natural frequency of the structure and excludes the higher natural frequencies.

The advantage of this application over unsuccessful attempts for MEMS accelerometer-based structural health monitoring is the required accuracy in the acceleration measurement. The measurement accuracy of the commercially available MEMS accelerometers is good enough for constructing restoring force characteristics.

Summary

MEMS sensors for measurement of structure seismic response and their application are discussed. The principle of the measurement of displacement, velocity, and acceleration is illustrated through an analysis of an SDOF mass-spring system. Based on this analysis, the reason for the popularity of the MEMS accelerometers and their limitations are discussed. An example of a possible application of MEMS accelerometer sensor network is presented.

Introduction

Issues pertaining to the dynamic behavior of mixed in-height structures, and more specifically concrete-steel buildings, are presented. The term “mixed structures” denotes here buildings that consist of a lower and an upper part with different dynamic response characteristics. When such structures are subjected to a dynamic excitation, e.g., an earthquake, they respond in a different way than more uniform structures; thus, their dynamic analysis and seismic design must account for these peculiarities.

The dissimilarity in the dynamic response characteristics of the two parts can be due to several factors. It may occur due to different lateral force resisting systems in the upper and lower part, or it might be the result of the action of seismic isolation or energy dissipation devices. One of the most common causes, which is the coexistence of different construction materials leading to nonuniform damping and elastoplastic behavior over the height of the building, is studied here.

More specifically, this section is devoted to modeling and analysis issues of structures consisting of a lower part made of concrete that

rests on the ground and supports an upper part made of steel. A schematic representation of such a structure is shown in Fig. 1. The lower part in the pertinent bibliography is usually referred to as primary structure and is denoted with the letter *p*, while the upper part is called secondary structure and is denoted with the letter *s*. Emphasis is directed here towards the different damping characteristics of the two parts, as reinforced concrete structures are known to exhibit higher damping than steel structures. Without loss of generality, it

is assumed that the concrete and steel parts have damping ratios equal to 5 % and 2 %, respectively, which are values commonly encountered in design codes for these two materials.

This configuration is very common in the case that an addition of floors occurs sometime in the life span of a building originally made of concrete, where, for reasons of speed of construction and reduction of inertia forces and floor mass or merely for architectural reasons, the added floors are made of steel (Fig. 2). Other typical examples

Mixed In-Height Concrete-Steel Buildings Under Seismic Actions: Modeling and Analysis, Fig. 3 Telecommunications tower made of steel mounted on concrete building

Mixed In-Height Concrete-Steel Buildings Under Seismic Actions: Modeling and Analysis, Fig. 4 Typical stadium configuration with concrete seats and steel cover

of mixed in-height structures are the cases of concrete buildings with telecommunication towers mounted on top of them (Fig. 3) and stadiums with the structures supporting the spectator's seats made of concrete and covered by a steel truss canopy (Fig. 4). Thus, mixed

concrete-steel structural systems are widespread and offer in many occasions desirable solutions due to architectural, structural, and functional reasons.

As a result, there are numerous structures with mixed concrete-steel configuration, having parts

Mixed In-Height Concrete-Steel Buildings Under Seismic Actions: Modeling and Analysis, Fig. 5 Typical MDoF structure configured in one material

that, during a seismic event, exhibit different damping and dissipate energy in different ways. Given that the pertinent seismic design regulations refer to structures consisting of only one material and specify accordingly analysis and design rules, the modeling, calculation of seismic actions, analysis, and design of mixed in-height concrete-steel buildings require a different treatment. The aim of this section is to investigate analysis possibilities of such mixed structures in ways similar to the ones followed for typical homogeneous structures, e.g., with methods that engineers are well acquainted with.

Fundamental Seismic Engineering Concepts

A typical multi-degree of freedom (MDoF) structure consisting of only one structural material, like the one shown in Fig. 5, is the case usually encountered in engineering practice and fully covered by pertinent seismic codes in terms of analysis and design specifications. The seismic oscillation of a structure with n degrees of freedom is described by Eq. 1, where the ground motion is denoted with $\ddot{x}_g$; the displacement

with x ; M , C , K are the mass, damping, and stiffness matrices, respectively; and r is a unit vector. The damping matrix here represents a typical Rayleigh type damping and can be easily produced using the mass and stiffness matrices.

$$M\{\ddot{x}\} + C\{\dot{x}\} + K\{x\} = -M\{r\}\ddot{x}_g \quad (1)$$

This equation is easy to handle and may be solved to obtain the response of the structure in a manner of ways, widely implemented and incorporated in commercial software. For example, the equation itself can be solved in the time or in the frequency domain, yielding thus the time history of the response in terms of total accelerations or displacements at each degree of freedom. Furthermore, a choice closer to engineering practice is to perform an eigenvalue analysis using the mass and stiffness matrices of Eq. 1 and thus obtain the modal quantities of the structure. Next, each mode is analyzed separately as a single degree of freedom (SDoF) structure as in Eq. 2, where q , ω , Γ are the response, eigenfrequency, and participation factor of each mode.

$$\ddot{q}_i + 2\zeta_i\omega_i\dot{q}_i + \omega_i^2q_i = -\Gamma_i\ddot{x}_g, \quad i = 1, 2, \dots, n \quad (2)$$

After formulating Eq. 2, it is possible either to analyze it also in the time or frequency domain and thus obtain the time history of the response of each mode or to estimate the maxima of each modal response via the use of a response spectrum, like the ones defined by EC8 (European Committee of Standardization 2004) and shown in Fig. 6. Then, by means of superimposing the modal maxima, it is possible to obtain the maxima of the overall response.

Peculiarities in the Seismic Response of Mixed Structures

In contrast to the case of typical structures consisting of only one material, the dynamic analysis of irregular structures made of concrete

**Mixed In-Height

and steel as the ones schematically shown in Fig. 1 is not straightforward. The difficulties occur already from the beginning, when forming the equation of motion. Unlike the case of uniform structures, where the damping matrix of Eq. 1 can be easily produced by the mass and stiffness matrices, now a rather cumbersome procedure must be followed in order to produce a damping matrix that manages to represent the actual damping distribution of the structure. During this approach, which is not supported by readily available commercial software, two separate damping matrices of Rayleigh type are formed, one for each part of the structure, which are then merged into a single matrix to be used in Eq. 1.

Then, the equation of motion itself cannot be decoupled in real-valued modal equations of motion like in Eq. 2. Instead, complex-valued modes occur, leading thus to complex-valued eigenfrequencies and modal damping ratios as well as modal participation factors. Moreover, should someone neglect the above and try to implement a typical spectral analysis using code compatible or even seismic spectra, the dilemma of choosing a single universal damping ratio comes up, which may alter significantly the response, as shown in the comparison of the EC8 compatible elastic spectra for damping values of 5 % and 2 %, shown in Fig. 7.

Thus, a common engineering analysis problem turns into a very complex one. As a result,

Mixed In-Height Concrete-Steel Buildings Under Seismic Actions: Modeling and Analysis, Fig. 8 Decoupled analysis procedure

and in order to avoid out of the ordinary analysis procedures, the common practice for such cases of irregularity is to make conservative assumptions for the damping ratios, which then leads to overestimation of the response. Due to the frequency with which such irregular structures are encountered, a significant amount of research has been carried out in order to provide analysis solutions that are compatible with common engineering practice.

An interesting approach that has been developed in that direction is the decoupled analysis of such structures. In this procedure the irregular structure is actually divided in two homogeneous parts, and each of them is analyzed separately, as

shown in Fig. 8, in contrast to the typical coupled analysis procedure shown in Fig. 9. In the decoupled procedure, the ground acceleration is induced in the concrete part, and its response is then used as a fictitious excitation for the steel part of the structure. The advantage of this method is that in each step the structural part analyzed is homogeneous and therefore typical analysis techniques are applicable. The disadvantage is that the so-called decoupling error is introduced, due to the fact that the analysis is not carried out in the actual structure.

An analytical prediction of this decoupling error for the case of harmonic excitations has been attempted (Chen and Wu 1999), by

Mixed In-Height Concrete-Steel Buildings Under Seismic Actions: Modeling and Analysis, Fig. 9 Coupled analysis procedure

introducing for that purpose a 2-DoF oscillator and thus managing a limited connection to MDoF structures, while analytical solutions for the decoupling error based on a complex-valued process are also provided (Gupta and Tembulkar 1984a, b).

In a modification of these approaches (Papageorgiou 2010a; Papageorgiou and Gantes 2005), the decoupling error is investigated numerically, by performing time history analyses of the 2-DoF model, so that other issues can be taken into account, such as inelastic material behavior as well as nonharmonic excitations including earthquake accelerograms. The analyses are also based on 2-DoF oscillators, but the results are efficiently correlated to MDoF structures by means of assigning the first mode characteristics of each part, i.e., modal mass and eigenfrequency, to the dynamic characteristics of each degree of freedom of the 2-DoF model, as

shown in Figs. 10 and 11. Moreover, graphical tools are produced allowing the prediction of the decoupling error at a preliminary design level, as will be shown next.

In the case that the errors arising from the decoupling procedure are above acceptable limits, a coupled analysis of the irregular structure is the proper solution. In this case and in order to avoid the adoption of a conservative damping ratio, the possibility of using equivalent damping ratios has been thoroughly investigated. By means of such ratios, the exact analysis of the structure, which is difficult to handle with readily available commercial software, is substituted with approximate analyses (Bilbao et al. 2006; Papagiannopoulos and Beskos 2009, 2006), even for the specific case of composite concrete-steel structures (Huang et al. 1996). More specifically, for the case of irregular concrete-steel structures, the results of numerical time history analyses

Mixed In-Height Concrete-Steel Buildings Under Seismic Actions: Modeling and Analysis, Fig. 10 Partition of the mixed structure and modal analysis of each part

Mixed In-Height Concrete-Steel Buildings Under Seismic Actions: Modeling and Analysis, Fig. 11 Formation of the equivalent 2-DoF oscillator

over a wide range of dynamic characteristics of the two parts permitted the development of graphical tools proposing equivalent damping ratios, both modal and uniform for the entire structure (Papageorgiou and Gantes 2008a, b, 2010b, 2011), as will be presented in the following.

Decoupling

As explained above, a common way to overcome the difficulties in the analysis and design of irregular concrete-steel structures is to divide them in two homogeneous parts and analyze each part separately. The concrete primary structure is analyzed first and its response at the support level of the secondary structure is then used as a fictitious excitation for the steel secondary structure. This decoupled procedure resembles the provisions of current seismic codes relevant to appendages, with the drawback that these provisions cannot be implemented in the case of superstructures with significant masses like the added steel floors

Mixed In-Height Concrete-Steel Buildings Under Seismic Actions: Modeling and Analysis,

Fig. 12 Spectra of the seismic records used and comparison of their envelope to EC8 compatible spectrum

of structures schematically represented in Figs. 1, 2, 3, and 4. This division also allows different engineering teams to undertake the design of each part, thus allowing offices specialized in constructions of each material to undertake the analysis and design of each relevant part of the structure.

The disadvantage of the decoupled procedure is that in either of its two analysis stages, the structure analyzed is a part of the real one and not the actual structure with its full mass, damping, and stiffness matrices. Thus, the interaction of the two parts is neglected and an error is introduced, in the prediction of the response of both the primary and the secondary structure. In order to have a reliable and safe, i.e., conservative, prediction of the decoupling error, a thorough investigation has been carried out in order to obtain its distribution for a wide range of dynamic characteristics of the two parts of the structure.

For that purpose, the 2DoF representation illustrated in Fig. 11 has been implemented. From the fundamental eigenfrequencies and the corresponding modal masses of the two parts, two ratios are defined, namely, the eigenfrequency and the mass ratios of secondary to primary structure, R_ω and R_m , respectively, as in Eq. 3. Thus, an (R_ω, R_m) plane can be defined containing a wide range of ratio pairs correlated through

the first mode dynamic quantities to a wide range of irregular structures.

$$R_m = \frac{M_s}{M_p}, R_\omega = \frac{\omega_s}{\omega_p} \quad (3)$$

For the specific case where earthquake excitations are considered, a range of seismic records have been chosen based on the dispersion of the frequencies they resonate the most, and they have been used in the analyses. More specifically, the records were chosen from seismic events in Greece as well as other seismic active areas of the world, and they were selected so as to produce a group of spectra enveloping the code prescribed ones, as shown in Fig. 12.

For each point in the (R_ω, R_m) plane, the corresponding structure is analyzed both approximately, with a decoupled analysis, and “exactly,” with a coupled analysis. Thus, the decoupling error is calculated for all points of the (R_ω, R_m) plane, i.e., for the chosen wide range of dynamic characteristics of the irregular structures, as described in Eq. 4 for all levels of the structure. Three reference error levels are chosen, namely, 10 %, 20 %, and 30 %, and the points of the (R_ω, R_m) plane at which these error levels appear are noted. Finally, the envelope of these points is plotted in a set of curves named decoupling curves, one for each error level, as

Mixed In-Height Concrete-Steel Buildings Under Seismic Actions: Modeling and Analysis,
Fig. 13 Seismic decoupling curves for the primary structure

Mixed In-Height Concrete-Steel Buildings Under Seismic Actions: Modeling and Analysis,
Fig. 14 Seismic decoupling curves for the secondary structure

shown in Fig. 13 for the concrete part and in Fig. 14 for the steel part of the irregular structure.

$$e = \left| \frac{\max(|\ddot{x}^{\text{dec}}|) - \max(|\ddot{x}^{\text{coup}}|)}{\max(|\ddot{x}^{\text{coup}}|)} \right| \quad (4)$$

These decoupling curves may be of use at a preliminary design stage, when the decision has to be taken whether to proceed with the decoupled or the coupled analysis procedure. At this stage and after the conceptual design of the structure has been concluded, modal analyses of each part of the structure can be carried out. Thus, the R_ω and R_m ratios can be defined so that the

structure can be positioned as a point in the (R_ω, R_m) plane. If the point representing the structure lies to the left of a curve, it means that the expected decoupling error is smaller than the one predicted by this specific curve, while if it is on the right, it means larger expected error. Hence, with a maximum error tolerance defined and with the decoupling error prediction by the curves of Figs. 13 and 14, the decision whether to proceed with decoupling can be taken.

The fact that the decoupling curves of Figs. 13 and 14 have been constructed as envelopes of the points arising from each seismic record makes them a conservative, and thus safe, prediction of the decoupling error. The veracity of this claim is

Mixed In-Height Concrete-Steel Buildings Under Seismic Actions: Modeling and Analysis,

Fig. 15 Comparison between actual error and prediction from seismic decoupling curves for the primary structure

Mixed In-Height Concrete-Steel Buildings Under Seismic Actions: Modeling and Analysis,

Fig. 16 Comparison between actual error and prediction from seismic decoupling curves for the secondary structure

tested over an irregular structure comprised by a two-floor steel superstructure mounted atop of a three-story concrete substructure, as the example shown in Fig. 1. In order to test the efficiency of the decoupling curves towards a conservative prediction of the decoupling error, a series of analyses is performed with the first modes of the two parts being in resonance. This is the worst-case scenario for the decoupling error, and the

structure of Fig. 1 is modified accordingly in order to be tested over a range of mass ratios. The decoupling error is monitored and shown in Fig. 15 for the primary structure and in Fig. 16 for the secondary structure. In order to provide an assessment of the efficacy of the decoupling curves, the points of the decoupling curves of Figs. 13 and 14 for $R_\omega = 1$ are shown in the respective colors.

**Mixed In-Height
Concrete-Steel Buildings
Under Seismic Actions:
Modeling and Analysis,**
Fig. 17 First mode
damping ratio

As seen from Figs. 15 and 16, the decoupling curves manage a conservative prediction of the decoupling error for the specific mass ratios. Even considering the worst-case scenario exhibited above, i.e., that of resonance between primary and secondary structures, the error prediction actually coincides with the actual error of the superstructure (Fig. 16), while it is very conservative as far as the primary structure is concerned (Fig. 15). Therefore, the developed decoupling curves can be a useful and at the same time safe tool at a preliminary design stage of analysis in order to enable decision taking whether to proceed with coupled or decoupled analysis.

Equivalent Modal Damping Ratios

It is evident from Figs. 13 and 14 that there are areas of the (R_ω, R_m) plane, i.e., irregular structures with certain combination of dynamic characteristics of the two parts, for which the decoupling error is larger than 30 %. Furthermore, as shown in Fig. 16, this error can be disproportionately large for $R_\omega = 1$ and large R_m values. In such cases, the decoupled analysis procedure is not acceptable. Thus, in order to

overcome the coupled analysis difficulties of an irregular structure consisting of two parts with different damping ratios, in this section equivalent damping ratios are proposed, suitably defined so as to effectively approximate the actual response by means of typical analysis that can be performed using commercially available software.

Initially, for each point in the (R_ω, R_m) plane, i.e., for each corresponding irregular structure, the complex damping ratios that normally occur from the complex-valued modal analysis are modified to real-valued ones, by simply adopting their absolute value. The distribution of the modal damping ratios for the first two modes of the structure over the (R_ω, R_m) plane is shown in Figs. 17 and 18.

As in the case of the decoupled analysis, the use of the absolute value of the complex damping ratios in a common real-valued modal analysis described in Eq. 2 also introduces an error, since the correct approach requires an analysis procedure that is complex valued in all steps. This error is again quantified for structures covering all points in the (R_ω, R_m) plane, as shown in Eq. 5 in terms of displacements, for all structure levels. For every point of the (R_ω, R_m) plane, i.e., for every structure investigated, the absolute value of

for the primary structure

these errors is obtained for each seismic record used, and the envelopes of the maxima are presented in Figs. 19 and 20.

$$e = \frac{\max(x^{\text{appr}}) - \max(x^{\text{exact}})}{\max(x^{\text{exact}})} \quad (5)$$

The fact that the error distribution both for the primary structure and for the secondary one is

sufficiently small, at least for a preliminary design level, encourages the adoption of the equivalent damping ratios in the analysis of actual irregular structures. For the structure with two steel floors mounted atop of three concrete levels, schematically shown in Fig. 1, with such dynamic characteristics of the two parts that lead to $R_\omega = 1$ and $R_m = 0.5$, i.e., a case that the two parts are in resonance, the maximum total

Mixed In-Height Concrete-Steel Buildings Under Seismic Actions: Modeling and Analysis, Fig. 20 Error envelopes for the secondary structure

Mixed In-Height Concrete-Steel Buildings Under Seismic Actions: Modeling and Analysis, Fig. 21 Total acceleration profile for a five-story irregular structure

acceleration distribution has been compared between the actual response and the one arising from the adoption of the equivalent modal damping ratios, and the results are shown in Fig. 21. Moreover, in order to allow comparison with common engineering practice, the distribution obtained by the adoption of overall damping ratios equal to 2 % and 5 % is presented as well. The good performance of the proposed equivalent damping ratios is evident.

Mixed In-Height Concrete-Steel Buildings Under Seismic Actions: Modeling and Analysis, Fig. 22 Error profile for a five-story irregular structure

Furthermore, in order to demonstrate the effectiveness of the proposed equivalent damping ratios, the error distribution as defined in Eq. 6, in absolute values, over the profile of the structure, is presented in Fig. 22. Along with the error occurring from the modification of the complex-valued damping ratios in order to be used in a real-valued modal analysis, the error that would occur should the damping ratio be assumed to have overall values equal to 2 % or 5 %, again in absolute values, is presented also. It is made clear that the complex-valued modal

Modeling and Analysis,**
Fig. 23 Error variation
with respect to the uniform
damping ratio

damping ratios, suitably modified in order to be used in a common, real-valued, modal analysis procedure, give totally acceptable results, and thus, the whole process is deemed suitable to be adopted in engineering practice. Moreover, the fact that there is readily available commercial software capable of performing structural analysis allowing the specification of modal damping ratios enhances the application prospects of the above-described procedure.

$$e = \left| \frac{\max(\ddot{x}^{\text{appr}}) - \max(\ddot{x}^{\text{exact}})}{\max(\ddot{x}^{\text{exact}})} \right| \quad (6)$$

Equivalent Uniform Damping Ratios

In an effort to provide engineers with equivalent damping ratios that are even closer to engineering practice compared to the modal ones, uniform damping ratios that apply to the whole structure and not just to certain modes are proposed next. In order to come up with these uniform equivalent damping ratios for each structure of the (R_ω, R_m) plane, a trial and error procedure is followed during which the set of possible uniform damping ratios between 0.02 and 0.05 with a step of 0.001 is tested and the response at each level of the structure is compared to the actual one.

In order to increase the accuracy of this procedure, the efficacy of the proposed uniform

damping ratios is tested independently for the primary and the secondary structure, in terms of total accelerations and displacements, and the dependence of the error on the damping ratios is shown in Fig. 23. The value of equivalent damping ratio within the above range that minimizes the error in the prediction of the response of the structure, whether in terms of accelerations or in terms of displacements, is chosen as optimum and used as equivalent uniform damping ratio for obtaining the corresponding response quantity.

This procedure is carried out for all points of the (R_ω, R_m) plane, i.e., for irregular structures with a wide range of dynamic characteristics, and for each point the optimum damping ratio in terms of total accelerations and displacements is noted for the concrete and the steel part of the structure. Thus, a distribution of proposed equivalent damping ratios is obtained in terms of total accelerations and displacements in the primary and the secondary part of the structure, as shown in Figs. 24, 25, 26, 27, 28, 29, 30, and 31, along with the corresponding errors.

The error distributions are sufficiently small in this case as well, and thus, their adoption instead of the actual damping distribution is recommended. For the irregular structure of Fig. 1, and for the specific case $R_\omega = 1, R_m = 0.5$, i.e., a case that the two parts are in resonance, the response of the structure using the proposed equivalent damping ratios is tested against the actual response.

M

More specifically, the structure is analyzed two times, each time with the proposed damping ratios for each part, and the displacement profile is constructed as a synthesis of the occurring profiles from each corresponding part. Thus, the total response is obtained and also compared with the response that would occur should overall damping ratios equal to 2 % and 5 % be selected in Fig. 32, while in Fig. 33 the absolute error profiles are compared. A similar approach would be needed to compute accelerations.

Thus, it is evident that even the uniform damping ratios occurring from a trial and error procedure can be applied instead of the adoption of the actual damping distribution. Furthermore,

the uniform damping ratios are even closer to engineering practice and may be applied in a response spectrum analysis procedure, where the response occurs by using accordingly produced spectra taking into consideration the proposed damping ratios.

Summary

Despite the frequency with which irregular concrete-steel structures are encountered in engineering practice, there are still no code provisions regarding their seismic design. As a result, intense research efforts have been directed towards

Mixed In-Height Concrete-Steel Buildings Under Seismic Actions: Modeling and Analysis, Fig. 32 Displacements profile for a five-story irregular structure

Mixed In-Height Concrete-Steel Buildings Under Seismic Actions: Modeling and Analysis, Fig. 33 Error profile for a five-story irregular structure

supplying answers to the problems arising in such cases. These efforts, as presented here, have started providing results that are very useful for engineering practice, aiming at developing tools that can be used by structural analysis and design teams using available commercial software.

These results come in the form of decoupling criteria, aiming at helping engineers to decide whether they can proceed with a convenient decoupled analysis or not, while in the case that

the decoupling error is intolerable, equivalent damping ratios are proposed, modal as well as uniform ones. Still, further research is necessary in order to cover various issues, regarding, for example, structures that are torsionally sensitive or have nonuniform concrete and steel parts, so that higher vibration modes are significant to the overall response, or aiming to address the differences in the elastoplastic behavior of the two parts.

Introduction

The current entry attempts to synoptically guide the reader through the merits and critical details of modal analysis having a particular focus on earthquake engineering, which is the main subject of this encyclopedia. Tracking the history of modal analysis, the conception of vibration modes dates back to the eighteenth century and the pioneering studies and debates of Daniel and John Bernoulli, Euler, and d'Alembert (see Kline 1990) who while studying the problem of the vibration of a taut string came up with the notion of the modal shape contributions that build up the total observed oscillations. Such revolutionary for the time vibration knowledge along with a systematic treatment and practical extensions of modal analysis topics, more focused on continuous systems, appeared first in a very concerted way in the historical "Theory of Sound" by Lord Rayleigh (1877). Much later, today, the term modal analysis is used with different context in engineering language depending on the engineering stream and application ranging from the simple eigenvalue analysis, which recovers the normal mode frequencies and shapes, to the complex experimental dynamic properties identification. Its typical and closest to earthquake engineering definition refers to the ensemble of theoretical tools and operations, which are employed in simplifying the dynamic response calculation of a very large extended structural system under generic time-dependent loading. A much wider picture of modal analysis encompassing apart from the previous side a vast experimental background that has an invaluable contribution in understanding, enhancing, and controlling structures pertains primarily in mechanical engineering. This latter broad view was captured for the first time in a very holistic manner by a seminal book publication by Ewins (1984), which was later succeeded by similar influential titles like the ones by his students Maia et al. (1997) and He and Fu (2001).

The description that follows does not intend to be an alike broad exhaustive review of the so-called *experimental* or *operational modal analysis*, and the reader is suggested to refer to

the quoted titles for this purpose. The definition assumed herein is closer to the first solely analytical approach, and as such it was previously very effectively included in the fundamental dynamics handbooks by Biggs (1964), Clough and Penzien (1993), and Chopra (1995) or in latest educational dynamics literature like Rajasekaran (2009). There the main attributes, limitations, and benefits of expressing a discretized structure's response to some random or deterministic dynamic excitation (earthquakes being an ideal generic example) as the superposition of modal responses are discussed and exemplified through practical exercises. The influence of damping in the modal decomposition process along with the crucial question of how many modes are needed in accurately reproducing the full dynamic information hidden in response metrics are meticulously addressed for becoming a tool in the hands of practicing structural engineers. The presentation that follows collects and reproduces a synopsis of all this essential digested knowledge, which is of high priority for seismic analysis and design. This information directly links to other entries of the encyclopedia and allows their better understanding and connection. Although it aims to be a self-contained entry, it is founded on some previous knowledge of structural modeling and the dynamics of single-degree-of-freedom (SDOF) and multi-degree-of-freedom (MDOF) systems, which are presented assuming the reader was previously exposed to basic vibration textbooks.

The entry begins with the study of a typical linear undamped n -degree-of-freedom system (with the application of multistory buildings always in mind) under a common form of dynamic loading. This system, in a straightforward manner, is transformed to n independent/uncoupled generalized SDOF systems acted upon by certain fractions of the initially defined loading, and two different approaches are introduced for performing any further practical analysis. Subsequently, findings are extrapolated to a variously damped viscous system (the proportional or classical and the generic or nonclassical), which is a very useful and effective approximation of the energy dissipation mechanism even in

complex structures consisting of many interconnecting nonuniform parts. The alternatives of working either in the time or frequency domain are both discussed in brief. For the subsequent main topic of modal truncation that emerges, where one has to decide the minimum number of modes r ($r < n = \text{number of degrees of freedom}$) that suffice for a sufficiently accurate reduced representation of the dynamic solutions (which may be displacements, rotations, cumulative shear forces, moments, etc.), all main different approaches and practices are presented. Miscellaneous details on various alterations of the analysis (e.g., mode acceleration or mode displacement form) practiced for increasing its numerical efficacy together with connections to aseismic structural design and brief essential reference to valuable extensions (e.g., nonlinear systems, health monitoring, and control) are provided throughout.

Modal Analysis Basics

The Undamped/Conservative System

The topic of dynamic-degree-of-freedom (DOF) selection, which is typical when transforming continuous systems to discrete models, along with reference to *nonholonomic* systems (i.e., where independent motion coordinates are essentially accompanied by additional constraints for fully determining motion) is not pursued herein. For the presentation in hand, the simple form of the already discrete engineering models assumed yield such discussions unnecessary. Thus, for this point, imagine a simplified n -degree-of-freedom discrete undamped structural model relieved by any *gyroscopic effects*. Such can be the translational toy mechanical system in Fig. 1a or the sway multistory shear frames in Fig. 1b, c.

In all cases depicted in Fig. 1, the envisaged finite degrees of freedom (DOFs) necessary are clearly designated. For all systems additional assumptions (e.g., rigid beams, massless columns, and springs) were employed for reducing the required DOFs. The set of governing equations of motion may be put, by either following the force equilibrium approach on n free-body

Modal Analysis, Fig. 1 MDOF structural models (a) toy mechanical discrete system (b, c) multistorey sway shear frames

diagrams or the energy approach, in the matrix form

$$\mathbf{M}\ddot{\mathbf{u}}(t) + \mathbf{K}\mathbf{u}(t) = \mathbf{F}(t), \quad (1)$$

where $\mathbf{M}$ and $\mathbf{K}$ are the constant symmetric mass and stiffness matrices ($n \times n$) $\ddot{\mathbf{u}}(t)$ and $\mathbf{u}(t)$ are the column matrices or vectors ($n \times 1$) of accelerations and displacements expressed in physical coordinates varying with time t and $\mathbf{F}(t)$ the vector ($n \times 1$) of the externally applied (not motion-dependent) dynamic loads. As a convention, all matrices are herein denoted by bold letters, while common letters are used to denote scalar magnitudes. Regarding the stiffness matrix $\mathbf{K}$, we must notice that it encompasses both the elastic and geometric stiffness information of the structural model, e.g., forces causing buckling are assigned to geometric stiffness. Also the constant nature of $\mathbf{K}$ translates to a linear elastic operational regime. As it can be easily verified through all Fig. 1 examples, for $\mathbf{M}$ it is straightforward to make it diagonal using the so-called *lumped mass* form, where translational DOFs are defined on each discrete mass. Yet this, which is not always possible or practical, will generally result in a non-diagonal $\mathbf{K}$ and, thus, in statically coupled Eq. 1, with the term *statically coupled* meaning

that each of the constituting linear equations of motion includes components of the displacement vector $\mathbf{u}(t)$ corresponding to various DOFs and not only the DOF referred to the existing component of the acceleration vector $\ddot{\mathbf{u}}(t)$. This coupling is in fact a coordinate coupling that perplexes the solution of Eq. 1 especially in the common case of large n . Alternatively, a different formulation practiced in finite element (FE) derivations for either $\mathbf{M}$ or $\mathbf{K}$, entitled *consistent form*, leads in general to non-diagonal forms for both these matrices, thereby leading to *statically and dynamically* coupled equations of motion. This means that each one of these equations includes components of the vectors $\mathbf{u}(t)$ and $\ddot{\mathbf{u}}(t)$ corresponding to various DOFs and not only to one DOF. And exactly, modal analysis aims at decoupling these equations. If Eq. 1 gets uncoupled, this will yield n independent equations of motion, i.e., each one of which refers to only one DOF, with the result that the MDOF system described by Eq. 1 can be treated as n equivalent uncoupled SDOF systems. Each of them corresponds to a so-called natural mode of vibration, which is characterized by a particular frequency and shape (modal/eigen frequency ω_i and modal/eigen vector $\boldsymbol{\varphi}_i$, ($n \times 1$)). Such an advantageous simplification can be established

by transforming the vector $\mathbf{u}(t)$ into a new vector $\mathbf{q}(t)$, ($n \times 1$), whose components are called normal or principal coordinates, as well as generalized displacements. This transformation is equivalent to the separation of variables technique, exercised in partial differential equations (PDEs), and is described as below

$$\mathbf{u}(t) = \Phi \mathbf{q}(t) = \sum_{i=1}^n \boldsymbol{\varphi}_i q_i(t), \quad (2)$$

or alternatively for the displacement vector $\mathbf{u}_i(t)$ corresponding to each individual mode i

$$\mathbf{u}_i(t) = \boldsymbol{\varphi}_i q_i(t). \quad (3)$$

In Eqs. 2 and 3, Φ is the modal matrix ($n \times n$) consisting of all n mode shapes $\boldsymbol{\varphi}_i$ arranged as its columns, which includes the entire modal shape information. And $\mathbf{q}(t)$ is a vector (i.e., column matrix) of n components, with the arbitrarily chosen i th component $q_i(t)$ representing the unknown time-functioning generalized displacement for the i th mode.

The modal parameters of frequency ω_i and shape $\boldsymbol{\varphi}_i$ are deduced by solving the so-called eigenvalue problem. This comes up when replacing Eq. 3 inside the free/unforced counterpart of Eq. 1 resulting from Eq. 1 after setting $\mathbf{F}(t) = 0$ and recognizing the pure harmonic nature of the associated $\mathbf{q}(t)$. Specifically speaking, considering the free/unforced counterpart of Eq. 1, i.e., the free-vibration equations

$$\mathbf{M}\ddot{\mathbf{u}}(t) + \mathbf{K}\mathbf{u}(t) = 0, \quad (4)$$

and assuming that each modal response $\mathbf{u}_i(t) = \boldsymbol{\varphi}_i q_i(t)$ is a solution to Eq. 4, it follows

$$\mathbf{M}\boldsymbol{\varphi}_i \ddot{q}_i(t) + \mathbf{K}\boldsymbol{\varphi}_i q_i(t) = 0, \quad (5)$$

which after premultiplying with the transposed mode shape vector $\boldsymbol{\varphi}_i^T$, i.e., a row matrix with the same elements as the column matrix $\boldsymbol{\varphi}_i$, gives

$$\boldsymbol{\varphi}_i^T \mathbf{M} \boldsymbol{\varphi}_i \ddot{q}_i(t) + \boldsymbol{\varphi}_i^T \mathbf{K} \boldsymbol{\varphi}_i q_i(t) = 0. \quad (6)$$

Now, defining the frequency ω_i as equal to

$$\omega_i^2 = \frac{\boldsymbol{\varphi}_i^T \mathbf{K} \boldsymbol{\varphi}_i}{\boldsymbol{\varphi}_i^T \mathbf{M} \boldsymbol{\varphi}_i}, \quad (7)$$

Equation 6 becomes equal to the harmonic vibration in $q_i(t)$

$$\ddot{q}_i(t) + \omega_i^2 q_i(t) = 0, \quad (8)$$

and combining with Eq. 5 results in

$$(\mathbf{M} - \omega_i^2 \mathbf{K}) \boldsymbol{\varphi}_i = 0, \quad (9)$$

which has a nonzero solution $\boldsymbol{\varphi}_i$ only for the zero determinant

$$|\mathbf{M} - \omega_i^2 \mathbf{K}| = 0. \quad (10)$$

Equation 10 is also termed the characteristic or frequency equation of the system. As expected due to the problem's indeterminate nature, the resulting vectors $\boldsymbol{\varphi}_i$ are not unique solutions but represent families of solutions of the form $\alpha \boldsymbol{\varphi}_i$, with α being an arbitrary scalar constant. The computational effort/time required for a solution is proportional to n^3 . It is noticed that deriving such sets of ω_i , $\boldsymbol{\varphi}_i$ solutions for large structural systems have introduced a whole new field for devising efficient solvers of Eqs. 9 and 10 (i.e., eigensolvers); the curious reader may consult §8 (Rades 2010). One of the most renowned equivalent numerical techniques of great application belongs to Rayleigh and Ritz (for some historical notes and disputes on its origins, one can read Leissa (2005)). Further, it is vital to refer to the important orthogonality properties, viz.,

$$\boldsymbol{\varphi}_i^T \mathbf{K} \boldsymbol{\varphi}_j = \boldsymbol{\varphi}_i^T \mathbf{M} \boldsymbol{\varphi}_j = 0 \text{ for all } i \neq j, \quad (11)$$

which result from the symmetrical form of the mass and stiffness matrices $\mathbf{M}$ and $\mathbf{K}$, respectively, and allow Eq. 1 to be uncoupled into n SDOF equations. Indeed, premultiplying Eq. 1 with $\boldsymbol{\varphi}_i^T$ and replacing $\mathbf{u}(t)$ with $\Phi \mathbf{q}(t)$ according to Eq. 2, one gets

$$\boldsymbol{\varphi}_i^T \mathbf{M} \ddot{\mathbf{q}}(t) + \boldsymbol{\varphi}_i^T \mathbf{K} \mathbf{q}(t) = \boldsymbol{\varphi}_i^T \mathbf{F}(t). \quad (12)$$

Owing to the orthogonality conditions, Eq. 12 becomes

$$\boldsymbol{\varphi}_i^T \mathbf{M} \ddot{q}_i(t) + \boldsymbol{\varphi}_i^T \mathbf{K} \boldsymbol{\varphi}_i q_i(t) = \boldsymbol{\varphi}_i^T \mathbf{F}(t), \quad (12a)$$

or equally

$$M_i \ddot{q}_i(t) + K_i q_i(t) = P_i(t), \quad (12b)$$

which after division with M_i becomes

$$\ddot{q}_i(t) + \omega_i q_i(t) = \frac{P_i(t)}{M_i}, \quad (12c)$$

where

$$K_i = \boldsymbol{\varphi}_i^T \mathbf{K} \boldsymbol{\varphi}_i, \quad M_i = \boldsymbol{\varphi}_i^T \mathbf{M} \boldsymbol{\varphi}_i, \quad (13)$$

$$\omega_i = K_i/M_i \text{ and } P_i(t) = \boldsymbol{\varphi}_i^T \mathbf{F}(t)$$

with K_i , M_i , ω_i and $P_i(t)$ being the so-called scalar modal stiffness, mass, frequency, and force, respectively. Note that combining orthogonality with Eq. 9 the typical SDOF relation, $K_i = \omega_i^2 M_i$ comes up. The values of K_i and M_i are subject to the scaling opted for the modal vectors $\boldsymbol{\varphi}_i$ and as such on their own are not very informative of the whole system. A common scaling, or else referred to as normalization, used for $\boldsymbol{\varphi}_i$ is the one that results in unit modal masses. Namely, if each $\boldsymbol{\varphi}_i$ is divided by $1/\sqrt{M_i}$, then evidently the second of Eq. 13 yields

$$\frac{\boldsymbol{\varphi}_i^T}{\sqrt{M_i}} \mathbf{M} \frac{\boldsymbol{\varphi}_i}{\sqrt{M_i}} = I. \quad (14)$$

With all the previous data in hand, one can now proceed with solving the initial problem of determining the response of the undamped system to some generic forcing $\mathbf{F}(t)$. The complete solution to Eq. 12b, which is a generalized SDOF equation, provides the part of the total response that owes exclusively to the i th mode and can be solved independently of all other modes. As is well known from the solution to an SDOF equation, the modal solution $q_i(t)$ of Eq. 12c consists

of a free-vibration solution $q_i^c(t)$ due to exclusively the initial conditions $q_i(0)$ and $\dot{q}_i(0)$ and a particular forced-vibration solution $q_i^p(t)$ due to exclusively the imposed modal force $P_i(t)$. Namely, the resultant solution $q_i(t)$ in the time domain equals

$$q_i(t) = q_i^c(t) + q_i^p(t), \quad (15)$$

with

$$q_i^c(t) = q_i(0) \cos \omega_i t + \frac{\dot{q}_i(0)}{\omega_i} \sin \omega_i t, \quad (16)$$

and

$$q_i^p(t) = \frac{1}{\omega_i} \int_0^t \frac{P_i(\tau)}{M_i} \sin \omega_i(t - \tau) d\tau. \quad (17)$$

The forced-vibration solution $q_i^p(t)$ described in the time domain by Eq. 17 is the Duhamel integral expression, for the calculation of which a number of numerical techniques (e.g., Newton-Cotes formulas, Simpson's rule, Romberg integration, etc.) may be employed. It is worth pointing out that recovering the modal initial conditions $q_i(0)$ and $\dot{q}_i(0)$ from the initial conditions $\mathbf{u}(0)$ and $\dot{\mathbf{u}}(0)$ can be a straightforward result of Eq. 2 and the orthogonality properties (11). Namely, by multiplying Eq. 2 with $\boldsymbol{\varphi}_i^T \mathbf{M}$ and taking into account the orthogonality properties (11), it follows that

$$\begin{aligned} \boldsymbol{\varphi}_i^T \mathbf{M} \mathbf{u}(0) &= \boldsymbol{\varphi}_i^T \mathbf{M} \Phi \mathbf{q}(0) \\ &= \boldsymbol{\varphi}_i^T \mathbf{M} \boldsymbol{\varphi}_i q_i(0) = M_i q_i(0), \end{aligned} \quad (18a)$$

$$\boldsymbol{\varphi}_i^T \mathbf{M} \dot{\mathbf{u}}(0) = \boldsymbol{\varphi}_i^T \mathbf{M} \Phi \dot{\mathbf{q}}(0) = \boldsymbol{\varphi}_i^T \mathbf{M} \boldsymbol{\varphi}_i \dot{q}_i(0) = M_i \dot{q}_i(0), \quad (18b)$$

from which the magnitudes $q_i(0) = \boldsymbol{\varphi}_i^T \mathbf{M} \mathbf{u}(0)/M_i$ and $\dot{q}_i(0) = \boldsymbol{\varphi}_i^T \mathbf{M} \dot{\mathbf{u}}(0)/M_i$ are derived.

Finally, after solving Eqs. 16 and 17 for the unknowns $q_i^c(t)$ and $q_i^p(t)$, and then Eq. 15 for the unknown $q_i(t)$, Equation 2 will be used for synthesizing the total response time histories $\mathbf{u}(t)$ from the individual synchronous modal

contributions $\mathbf{u}_i(t)$, which have been determined as the products $\boldsymbol{\varphi}_i q_i(t)$ of the evaluated modal shapes $\boldsymbol{\varphi}_i$ and generalized displacements $q_i(t)$. This writes as

$$\mathbf{u}(t) = \sum_{i=1}^n \mathbf{u}_i(t) = \sum_{i=1}^n \boldsymbol{\varphi}_i q_i(t). \quad (19)$$

The most valuable feature of Eq. 19 is that not all n terms of the sum are required for accurately representing the total response. A large-scale structure like a tall building has hundreds of DOFs, which will produce hundreds of natural modes. Yet, it is common that for typical operational loading conditions, the lower (i.e., of lower frequencies) few modes, whose number r is far smaller than the number n of all the DOFs of the structure, are enough to compute the vector $\mathbf{u}(t)$ by using Eq. 19, for the higher (i.e., of higher frequencies) modes of a structure are not excited considerably. The value of r , as well as to what extent it can be reduced with respect to n , is a function not only of the initial loading $\mathbf{F}(t)$'s characteristics (i.e., shape distribution and frequency content) and their match to specific natural modes but also of the response metric that needs to be considered. For instance, representation of dynamic moment, shear, and stress variables in general requires more natural modes than representing the displacement solutions. This finding that was meticulously exemplified in Chopra (1995, 1996) and Clough and Penzien (1993) owes primarily to the fact that higher-order response attributes need additional information for their description (analogous to the added information embedded in derivatives of a function compared to the actual function).

The Classical/Proportional Damping Addition

The conservative (i.e., undamped, i.e., without energy losses) system treated earlier is fundamental for any dynamic study. Yet, it is not completely accurate in representing reality. All structures have the inherent ability of damping with which they can dissipate energy inputs. As a matter of fact, apart from being a structural property, effective damping can also surface from the

interaction of the structure with environmental or other types of loads. Distinctive examples of such cases, also described as *self-excitation*, are the Tacoma Narrows Bridge collapse (with the associated pure torsional flutter) and the large lateral vibrations of London Millennium Bridge (with pedestrians acting as negative dampers). The damping property is almost impossible to faithfully model ab initio. This is a result of a multitude of reasons. There is little information on inherent material damping, and further energy dissipation can originate from sources like connections, crack openings, or inter-element friction that are really hard to capture entirely. The practical and plausible solution is to model damping as a linear viscous term $\mathbf{C}\dot{\mathbf{u}}(t)$, i.e., function of velocity, which efficiently provides a route toward changing the energy balance in the equations of motion. This will lead to modifying the set of Eq. 1 as follows:

$$\mathbf{M}\ddot{\mathbf{u}}(t) + \mathbf{C}\dot{\mathbf{u}}(t) + \mathbf{K}\mathbf{u}(t) = \mathbf{F}(t), \quad (20)$$

where $\mathbf{C}$ stands for the damping matrix ($n \times n$). This is in general non-diagonal. A work-around toward approximating the many unknown elements of $\mathbf{C}$ is to connect it to the straightforwardly derived structural matrices $\mathbf{K}$ and $\mathbf{M}$. The approximation of stiffness-proportional damping, which is actually appealing to intuition, can easily be shown to result in damping increasing with frequency. This is contrary to many experimental findings, which in general refute such a pattern. Mass-proportional damping on the other hand, which is simplistically linked to air/medium damping, also contradicts experience. However, combining the two proportionality approaches yields the so-called Rayleigh damping, which seems to constitute a good and much-used idealization for the energy dissipation mechanism of evenly distributed structures. A typical example of the latter is a multistory building of similar material and structural system throughout its height. According to the Rayleigh approach, $\mathbf{C}$ is given the form

$$\mathbf{C} = a_0 \mathbf{M} + a_1 \mathbf{K}, \quad (21)$$

where a_0 and a_1 are unknown scalar constants. Employing Rayleigh damping allows the classical modal decomposition (uncoupling) process earlier performed for the undamped case to apply to the damped case as well. Accordingly, one can firstly insert Eq. 2 in Eq. 20 and then multiply with the transposed mode shape vector $\boldsymbol{\varphi}_i^T$ derived from the undamped free-vibration Eq. 4 to get

$$\boldsymbol{\varphi}_i^T \mathbf{M} \Phi \ddot{\mathbf{q}}(t) + \boldsymbol{\varphi}_i^T (a_0 \mathbf{M} + a_1 \mathbf{K}) \Phi \dot{\mathbf{q}}(t) + \boldsymbol{\varphi}_i^T \mathbf{K} \Phi \mathbf{q}(t) = \boldsymbol{\varphi}_i^T \mathbf{F}(t). \quad (22)$$

Equation 22 due to Eqs. 11 and 13 becomes alike to Eq. 12

$$\boldsymbol{\varphi}_i^T \mathbf{M} \boldsymbol{\varphi}_i \ddot{q}_i(t) + \boldsymbol{\varphi}_i^T (a_0 \mathbf{M} + a_1 \mathbf{K}) \boldsymbol{\varphi}_i \dot{q}_i(t) + \boldsymbol{\varphi}_i^T \mathbf{K} \boldsymbol{\varphi}_i q_i(t) = \boldsymbol{\varphi}_i^T \mathbf{F}(t). \quad (22a)$$

Or alternatively

$$M_i \ddot{q}_i(t) + (a_0 M_i + a_1 K_i) \dot{q}_i(t) + K_i q_i(t) = P_i(t). \quad (22b)$$

In the last pair of equations, it should be noted that exclusively due to the fact that $\mathbf{C}$ was assumed to be a weighted sum of $\mathbf{M}$ and $\mathbf{K}$, orthogonality still applies and results in uncoupled modal damping expressions C_i for each mode i . Namely,

$$\begin{aligned} \boldsymbol{\varphi}_i^T \mathbf{C} \boldsymbol{\varphi}_j &= 0 \text{ for all } i \neq j \text{ and} \\ C_i &= a_0 M_i + a_1 K_i = \boldsymbol{\varphi}_i^T \mathbf{C} \boldsymbol{\varphi}_i. \end{aligned} \quad (23)$$

Equation 23 allows Eq. 22b to be rewritten as

$$M_i \ddot{q}_i(t) + C_i \dot{q}_i(t) + K_i q_i(t) = P_i(t), \quad (22c)$$

which after division with M_i becomes equal to

$$\ddot{q}_i(t) + 2\xi_i \omega_i \dot{q}_i(t) + \omega_i^2 q_i(t) = \frac{P_i(t)}{M_i}, \quad (22d)$$

with the modal mass and stiffness M_i and K_i , the modal frequency ω_i , and the modal force $P_i(t)$ defined by Eq. 13. As for the so-called

modal damping ratio (or fraction of the critical damping) ξ_i , it stands for the ratio $C_i/2\omega_i M_i$, i.e.,

$$\xi_i = C_i/2\omega_i M_i. \quad (24)$$

It is worth noting that Eq. 23 characterizes not only the Rayleigh damping model but also any damping model that offers the possibility for the classical modes of the undamped free vibration to be used in order to uncouple the equations of damped motion of the structure under consideration. Any such damping model is grouped as classical damping and substantially simplifies all subsequent dynamic calculations. Obviously, the subcases of mass-proportional and stiffness-proportional damping brought up earlier must also be categorized as classical damping.

Subsequently the process of calculating modal responses is identical to the previous description, where someone solves independently each modal equation and then synthesizes the total response by summing up the few lower modal contributions up to a certain order. The modal solution $q_i(t)$ of the Eq. 22 is now also affected by the modal damping as expressed by the modal damping ratio ξ_i . In analogy with Eqs. 15 up to 17, now the modal solution $q_i(t)$ generalizes to

$$\begin{aligned} q_i(t) &= q_i^c(t) + q_i^p(t) = \\ &= e^{-\xi_i \omega_i t} \left(q_i(0) \cos \tilde{\omega}_i t + \frac{\dot{q}_i(0) + \xi_i \omega_i q_i(0)}{\tilde{\omega}_i} \sin \tilde{\omega}_i t \right) \\ &\quad + \int_0^t \frac{P_i(\tau)}{M_i} h_i(t-\tau) d\tau, \end{aligned} \quad (25)$$

where $\tilde{\omega}_i$ is the so-called damped modal frequency, which stands for the multiple $\omega_i \sqrt{1 - \xi_i^2}$ of the undamped modal frequency ω_i , i.e.,

$$\tilde{\omega}_i = \omega_i \sqrt{1 - \xi_i^2}, \quad (26)$$

and $h_i(t - \tau)$ is the modal function known as unit-impulse response function given by

Modal Analysis, Table 1 Recommended damping values from Chopra (1995)

Type of structure	Damping ratio % (stress below ½ of yield)	Damping ratio % (stress at or just below yield)
Welded steel, prestressed concrete	2–3	5–7
Reinforced concrete (with considerable cracking)	3–5	7–10
Bolted steel, timber structures with bolted joints	5–7	10–15

$$h_i(t - \tau) = \frac{1}{\tilde{\omega}_i} e^{-\xi_i \omega_i (t - \tau)} \sin \tilde{\omega}_i (t - \tau). \quad (27)$$

In the above analysis, one step was tacitly skipped. When adopting the Rayleigh damping expression of Eq. 21, the unknown constants a_0 and a_1 need to be determined for the damping matrix to be fully described. Indicatively this can be done as follows:

The modal damping can be determined experimentally through analyzing response measurements. This is the exact inverse problem of what is dealt in this entry. In short an answer is enabled through different techniques, e.g., the half-power bandwidth method, the free decays of isolated modes, or some other more elaborate modal identification technique. In the absence of such experimental data, figures that have developed from long structural experience can be used. Such information is given in Table 1 noting the stress amplitude dependence.

With values for the modal damping ratios in hand, one can write Eq. 23 for two modes, customarily the first and the last one considered (i.e., r th), viz.,

$$\left. \begin{aligned} C_1 &= a_0 M_1 + a_1 K_1 = 2\omega_1 M_1 \xi_1 \\ C_r &= a_0 M_r + a_1 K_r = 2\omega_r M_r \xi_r \end{aligned} \right\}. \quad (28)$$

The latter system of two algebraic equations is then to be solved simultaneously for a_0 and a_1 . A further generalization of classical damping can

also be considered when more than two modal damping values are taken into account in capturing the damping distribution. Then we have the Caughey damping approach according to which C is expressed as

$$C = M \sum_{j=0}^{l-1} a_j (M^{-1} K)^j, \quad (29)$$

where l is the number of modal damping ratios to be used. Evidently for $l = 2$ this reduces to Rayleigh damping, while for $l = 3$ Eq. 29 results in

$$C = a_0 M + a_1 K + a_2 K M^{-1} K. \quad (30)$$

The l unknown constants are found again in a straightforward manner by solving a $l \times l$ system of algebraic equations.

The Nonclassical Damping Case

The classical damping approach although not physically realizable has found extensive use in engineering practice and particularly in standard earthquake engineering design. However, for structures that are heavily damped or unevenly distributed or even when they possess closely spaced modes, the couplings induced by the damping matrix may produce significant shortcomings and complications in the earlier presented modal analysis. An example of such a case, where nonclassical damping is to be expected, would appear in a nuclear reactor containment vessel founded on a soft soil. The quite different damping properties between the stiff structure and the foundation will induce a highly damped, very complex dynamic soil-structure interaction that establishes itself through a very generically shaped damping matrix (Clough and Mojtahedi 1976). For making things clear, in these instances the solution again starts from writing the damped equation of motion

$$M\ddot{u}(t) + C\dot{u}(t) + Ku(t) = F(t). \quad (20)$$

Still, what changes is that after substituting in the latter the modal decomposition indicated in Eq. 2

and premultiplying with the undamped mode vector $\boldsymbol{\varphi}_i^T$, one gets

$$\boldsymbol{\varphi}_i^T \mathbf{M} \boldsymbol{\varphi}_i \ddot{q}_i(t) + \boldsymbol{\varphi}_i^T \mathbf{C} \boldsymbol{\Phi} \dot{\mathbf{q}}(t) + \boldsymbol{\varphi}_i^T \mathbf{K} \boldsymbol{\varphi}_i q_i(t) = \boldsymbol{\varphi}_i^T \mathbf{F}(t) \quad (31a)$$

or alternatively

$$M_i \ddot{q}_i(t) + \boldsymbol{\varphi}_i^T \mathbf{C} \boldsymbol{\Phi} \dot{\mathbf{q}}(t) + K_i q_i(t) = P_i(t). \quad (31b)$$

Equation 31b obviously is a system of n -coupled equations, since the row vector $\tilde{\mathbf{C}} = \boldsymbol{\varphi}_i^T \mathbf{C} \boldsymbol{\Phi}$, ($1 \times n$), has in general nonzero elements that introduce in Eq. 31b apart from $\dot{q}_i(t)$ also terms $\dot{q}_j(t)$ with $j \neq i$. Thus, contrary to the principle and target of modal analysis, it is not possible to deal with n -independent generalized SDOF modal systems. It actually seems that there is no benefit in transforming the initial coupled equation of motion to its modal form using the undamped modes. There are a number of approaches to tackle this problem:

The first more simplistic approach disregards all the coupled contributions of Eq. 31b by essentially zeroing in the row vector $\tilde{\mathbf{C}}$ all elements apart from C_i , i.e., $\tilde{\mathbf{C}} = [0 \dots C_i \dots 0]$. Subsequently, the remaining analysis becomes identical to the above described for the classically damped case.

A different also approximate approach would be for one to keep all terms inside Eq. 31b and attempt to solve the system of coupled equations using numerical techniques, that is, direct integration (e.g., Newmark's method). More on the latter will appear in the entry of nonlinear systems. The relative benefit of employing Eq. 31b against applying direct integration to the initial n equations of damped motion described by the matrix Eq. 20 lies in the fact that due to generally few modes dominating response, a much reduced number of r equations can be considered. This is of great importance in large structural systems with thousands of DOFs.

Yet, both of the above analytical approaches may introduce errors of undefined magnitude. The most rigorous treatment of the problem is to uncouple the equations of motion using damped

modes instead of the undamped ones. Their derivation, indicatively provided herein, proceeds by first writing the free-vibration (unforced) counterpart of the forced-vibration matrix Eq. 20

$$\mathbf{M}\ddot{\mathbf{u}}(t) + \mathbf{C}\dot{\mathbf{u}}(t) + \mathbf{K}\mathbf{u}(t) = \mathbf{0}. \quad (32)$$

And then, assuming a solution of the form

$$\mathbf{u}_i(t) = \boldsymbol{\phi}_i e^{\lambda_i t}, \quad (33)$$

Equation 32 leads to

$$(\lambda_i^2 \mathbf{M} + \lambda_i \mathbf{C} + \mathbf{K}) \boldsymbol{\phi}_i = \mathbf{0}, \quad (34)$$

where λ_i and $\boldsymbol{\phi}_i$ are the damped eigenvalues and eigenvectors, respectively.

The methodology to solve Eq. 34 relies on the so-called state-space formulation. According to it, Eq. 34 may be rewritten as

$$\begin{bmatrix} -\mathbf{K} & \mathbf{0} \\ \mathbf{0} & \mathbf{M} \end{bmatrix} \begin{bmatrix} \lambda_i \boldsymbol{\phi}_i \\ \lambda_i^2 \boldsymbol{\phi}_i \end{bmatrix} + \begin{bmatrix} \mathbf{0} & \mathbf{K} \\ \mathbf{K} & \mathbf{C} \end{bmatrix} \begin{bmatrix} \boldsymbol{\phi}_i \\ \lambda_i \boldsymbol{\phi}_i \end{bmatrix} = \begin{bmatrix} \mathbf{0} \\ \mathbf{0} \end{bmatrix}, \quad (35)$$

and introducing the block matrices $\mathbf{A}$ and $\mathbf{B}$, ($2n \times 2n$), and column block vector $\mathbf{v}_i$, ($2n \times 1$), i.e.,

$$\mathbf{A} = \begin{bmatrix} -\mathbf{K} & \mathbf{0} \\ \mathbf{0} & \mathbf{M} \end{bmatrix}, \mathbf{B} = \begin{bmatrix} \mathbf{0} & \mathbf{K} \\ \mathbf{K} & \mathbf{C} \end{bmatrix} \text{ and } \mathbf{v}_i = \begin{bmatrix} \boldsymbol{\phi}_i \\ \lambda_i \boldsymbol{\phi}_i \end{bmatrix}, \quad (36)$$

reshapes Eq. 35 into

$$(\lambda_i \mathbf{A} + \mathbf{B}) \mathbf{v}_i = \mathbf{0}, \quad (37)$$

which has a nonzero solution $\mathbf{v}_i$ only for the zero determinant

$$|\lambda_i \mathbf{A} + \mathbf{B}| = 0. \quad (38)$$

The latter is an eigenvalue problem of order $2n$, which is known as the complex eigenvalue problem owing to the fact that both λ_i and $\boldsymbol{\phi}_i$ are in general complex valued. Before proceeding any further, it is worth noticing that the increased

order $2n$ of the complex eigenvalue problem in comparison with the order n of the classical eigenvalue problem requires an increased computational effort/time proportional to $(2n)^3 = 8n^3$ for a solution. This is the reason for this approach to be outside the main pursuits of applied structural dynamics. Now, returning to Eq. 38, if λ_i is a solution, then its conjugate is also one. Typically, λ_i is expressed as

$$\lambda_i = \omega_i \left(-\zeta_i + j\sqrt{1 - \zeta_i^2} \right), \quad (39)$$

where $j = \sqrt{-1}$ is the imaginary unit and ω_i and ζ_i are the modal frequency and modal damping ratio, respectively. The complex nature of the eigenvectors ϕ_i accounts for phase differences other than 0° and 180° between their components. Orthogonality relations now become

$$\mathbf{v}_i^T \mathbf{A} \mathbf{v}_j = \mathbf{v}_i^T \mathbf{B} \mathbf{v}_j = 0 \text{ for all } i \neq j, \quad (40)$$

which allow the uncoupling of Eq. 35 or of its forced counterpart. Having laid the ground for subsequent analysis (e.g., time response solutions), no additional details are presented herein, and the reader is suggested to consult relevant fundamental literature on this special topic for additional resources and worked examples, e.g., (Crandall and McCalley 2002; Itoh 1973; Hansen et al. 2012).

Member Forces

The procedures described above yielded the displacement time response, both modal and total, of a linear elastic structure. Yet, it is of great relevance for design purposes to derive also the force and stress developing on individual members/elements. There are two distinct ways to achieve this:

1. Having in hand the modal displacements $\mathbf{u}_i(t)$ along the structure, one can use the member stiffness properties in order to derive the modal force $R_i(t)$ on the member and subsequently the required stresses. Considering all the modal contributions, one can write

$$R(t) = \sum_{i=1}^r R_i(t), \quad (41)$$

which apart from forces also applies to the resultant stresses.

2. Alternatively the modal displacements $\mathbf{u}_i(t)$ can be used to define equivalent modal static forces

$$\mathbf{F}_i^s(t) = \mathbf{K} \mathbf{u}_i(t) = \omega_i^2 \mathbf{M} \mathbf{u}_i(t). \quad (42)$$

Solving the structure statically for the obtained $\mathbf{F}_i^s(t)$, which are now applied as external forces at each time instant, will give again the modal member force $R_i(t)$. All individual modal contributions again have to be added together in accordance with Eq. 41.

The Earthquake Problem

The general modal analysis background presented above will now shift the focus to the earthquake-loading scenario of a classically damped n -DOF structure. Such a structure could be a typical multistory frame, e.g., Fig. 1c, which is customarily used as a benchmark in similar studies. Earthquake loading is the result of seismic action of the ground on the supports of the structure, that is, the result of a vibration motion of the supports of the structure caused by an earthquake. Specifically speaking, the seismic action translates to a ground acceleration input $\ddot{u}_g(t)$ at the foundation level (this is in most instances horizontal but can also be vertical), whose transmission to the upper structure creates an equivalent dynamic force distribution that constitutes what is called earthquake loading. Disregarding the special topic of multiple support excitation (for such an extension, consult Clough and Penzien (1993) or Chopra (1995)), the earthquake (or seismic) load vector that enters the matrix equation of motion, Eq. 20, can be expressed as

$$\mathbf{F}(t) = -\mathbf{M} \mathbf{u} \ddot{u}_g(t). \quad (43)$$

The latter implies a synchronous though spatially varying loading of the different lumped masses. The vector $\mathbf{u}$, ($n \times 1$), is an influence vector of the ground motion on the structure and represents the displacements that will result for each DOF when a static unit ground displacement $u_g(t) = 1$, of the same direction as $\ddot{u}_g(t)$, is applied to an undeformed (absolutely rigid) model of the structure. For example, in the frame of Fig. 1b, considering a horizontal earthquake input, $\mathbf{u}$ becomes $[1 \ 1 \ 0 \ 0 \ 0]^T$, while for the frame of Fig. 1c, it turns to $[1 \ 1 \ 1 \ 1 \ 1]^T$. For proof purposes, Eq. 43 and the definition of $\mathbf{u}$ can naturally be derived when expressing the equilibrium at each mass of the MDOF structure in terms of the total displacement $\mathbf{u}_t(t)$, which evidently is the vector sum of the relative-to-base displacement $\mathbf{u}(t)$ and the ground/base displacement $\mathbf{u}_g(t)$, i.e.,

$$\mathbf{u}_t(t) = \mathbf{u}(t) + \mathbf{u}_g(t). \quad (44)$$

Indeed, the equilibrium of the masses of a seismically excited MDOF structure is expressed by

$$\mathbf{M}\ddot{\mathbf{u}}_t(t) + \mathbf{C}\dot{\mathbf{u}}_t(t) + \mathbf{K}\mathbf{u}_t(t) = 0, \quad (45)$$

and substituting $\ddot{\mathbf{u}}_t(t)$ in accordance with Eq. 24, it follows

$$\mathbf{M}\ddot{\mathbf{u}}(t) + \mathbf{C}\dot{\mathbf{u}}(t) + \mathbf{K}\mathbf{u}(t) = -\mathbf{M}\mathbf{u}\ddot{u}_g(t), \quad (46)$$

which proves that the seismic load vector $\mathbf{F}(t)$ equals $-\mathbf{M}\mathbf{u}\ddot{u}_g(t)$, thereby proving Eq. 32.

In a broader perspective, the expression for the seismic load can be generalized to describe a wider family of loading cases for which

$$\mathbf{F}(t) = \mathbf{s}f(t), \quad (47)$$

with the vector $\mathbf{s}$, ($n \times 1$), embodying all spatial variations and the scalar function $f(t)$ embodying all synchronous time variations. Trivially for $\mathbf{s} = -\mathbf{M}\mathbf{u}$ and $f(t) = \ddot{u}_g(t)$, one reverts to the earthquake-related problem.

This is actually the starting point for any subsequent analysis intending to obtain response histories. Yet, it must be noted that for most usual

practices in seismic calculations, a different characterization for the earthquake motion is opted. This is the instrumental approach of the so-called response spectra and attempts to remove the tedious numerical burdens that are related to obtaining all the history of the response of a specific structure to the long time sequence of the ground acceleration of a specific earthquake excitation in order that the maximum value of the response is evaluated. Namely, with response spectra, one only has to consider the maximum response output (this may be in terms of displacement, S_d , or velocity, S_v , or acceleration, S_a) that an SDOF system produces under a specific earthquake excitation. Thus, an earthquake is no more an explicit time function $\ddot{u}_g(t)$. It is described through its maximum effect on SDOF systems with specific natural frequency and damping. This approach best serves the engineering need for evaluating the strength of a structure against the maximum value of its response to a given seismic excitation.

Whatever the earthquake definition assumed and the analysis opted (time histories or response maxima), there are substantial benefits associated with the use of modal analysis. Yet, the inherent in response spectra need for a decomposition of an initial MDOF structure to equivalent SDOF ones makes modal analysis in that instance more than a beneficial feature an irreplaceable prerequisite.

Excitation and Participation Factors

In what follows, some essential notions relevant to the earthquake analysis of structures are developed through exemplifying the modal analysis application. Combining Eqs. 13 and 47 yields

$$\begin{aligned} P_i(t) &= \boldsymbol{\varphi}_i^T \mathbf{F}(t) = \boldsymbol{\varphi}_i^T \mathbf{s}f(t) \\ &= L_i f(t) \quad \text{with } L_i = \boldsymbol{\varphi}_i^T \mathbf{s}, \end{aligned} \quad (48)$$

as well as

$$\begin{aligned} \frac{P_i(t)}{M_i} &= \frac{\boldsymbol{\varphi}_i^T \mathbf{s}}{M_i} f(t) = \frac{L_i}{M_i} f(t) \\ &= \Gamma_i f(t) \quad \text{with } \Gamma_i = \frac{L_i}{M_i}, \end{aligned} \quad (49)$$

and, hence,

$$\Gamma_i = \frac{L_i}{M_i} = \frac{\boldsymbol{\varphi}_i^T \mathbf{s}}{M_i}. \quad (50)$$

The modal factors L_i and Γ_i are termed the *modal excitation factor* and the *modal participation factor*, respectively. It is easy to verify that the values of both the factors Γ_i and L_i depend on the normalization used for $\boldsymbol{\varphi}_i$ (since the ratio L_i/Γ_i equals the modal mass $M_i = \boldsymbol{\varphi}_i^T \mathbf{M} \boldsymbol{\varphi}_i$).

In view of Eq. 50 and the orthogonality conditions, it holds true

$$\boldsymbol{\varphi}_i^T \mathbf{s} = \Gamma_i M_i = \Gamma_i \boldsymbol{\varphi}_i^T \mathbf{M} \boldsymbol{\varphi}_i = \boldsymbol{\varphi}_i^T \sum_{j=1}^n \Gamma_j \mathbf{M} \boldsymbol{\varphi}_j, \quad (51)$$

which allows expanding of the vector $\mathbf{s}$ in terms of the modal contributions $\mathbf{s}_i$ as follows:

$$\mathbf{s} = \sum_{i=1}^n \mathbf{s}_i = \sum_{i=1}^n \Gamma_i \mathbf{M} \boldsymbol{\varphi}_i. \quad (52)$$

Evidently, the vector $\mathbf{s}$ and its modal components $\mathbf{s}_i$ are independent of the absolute magnitudes of $\boldsymbol{\varphi}_i$. The modal factors L_i and Γ_i naturally emerge when performing the modal analysis steps indicated in Eqs. 22c and 22d. Namely, when substituting for the load form adopted in Eq. 47 and writing the i modal matrix equation of motion, one gets

$$M_i \ddot{q}_i(t) + C_i \dot{q}_i(t) + K_i q_i(t) = L_i f(t), \quad (53a)$$

or equally

$$\ddot{q}_i(t) + 2\omega_i \xi_i \dot{q}_i(t) + \omega_i^2 q_i(t) = \Gamma_i f(t). \quad (53b)$$

The rationale behind the modal decomposition of the load distribution $\mathbf{s}$ lies in introducing inertial modal load contributions. To explain this, the inertial force in the i th mode is given as $\mathbf{M}\ddot{\mathbf{u}}_i$ or, taking into account Eq. 3, as $\mathbf{M}\boldsymbol{\varphi}_i \ddot{q}_i(t)$. The $\mathbf{M}\boldsymbol{\varphi}_i$ pre-factor, thus, makes apparent the underlying inertial concept linking to Eq. 52. Γ_i evidently from Eq. 53b is a weighting factor that scales the

load fraction to be assigned to each specific mode. The obscurity of the normalization dependence for Γ_i hinders it, becoming a direct clear indicator of the relative significance of the i th mode.

Relevant to this, the most important and useful feature of the expansion employed in Eq. 52 is that the load distribution $\mathbf{s}_i$ produces response exclusive to mode i or else that the response at each mode i owes solely to $\mathbf{s}_i$. This can be easily derived by observation of Eq. 52. When multiplying it with $\boldsymbol{\varphi}_j^T$ and $f(t)$ to create what is defined as the modal load $P_j(t)$ one gets

$$\begin{aligned} P_j(t) &= \boldsymbol{\varphi}_j^T \mathbf{s} f(t) \\ &= \sum_{i=1}^n \boldsymbol{\varphi}_j^T \mathbf{s}_i f(t) = \sum_{i=1}^n \Gamma_i \boldsymbol{\varphi}_j^T \mathbf{M} \boldsymbol{\varphi}_i f(t). \end{aligned} \quad (54)$$

This expression due to orthogonality yields a nonzero value only for $j = i$.

Contribution Factors (Chopra's Physical Interpretation)

Subsequently, if one follows the above procedures, the ensuing earthquake response problem can be solved. Yet, as first developed by Chopra (1995), a transformation is put forward that can further assist in a physical interpretation of modal analysis relevant to earthquake engineering. Namely, due to the linearity of the structural system, if one assumes

$$q_i(t) = \Gamma_i D_i(t), \quad (55)$$

then the modal Eq. 53b can be replaced by the equivalent

$$\ddot{D}_i(t) + 2\omega_i \xi_i \dot{D}_i(t) + \omega_i^2 D_i(t) = f(t), \quad (56)$$

which describes a unit mass SDOF system, with frequency ω_i and damping ξ_i loaded by $f(t)$; the latter can be either a force or a ground acceleration without any distinction. Accordingly, $D_i(t)$ is but the i th modal response of the system to the loading $f(t)$. The contribution of the i th mode to response can then be given by Eq. 3 as

$$\mathbf{u}_i(t) = \boldsymbol{\varphi}_i q_i(t) = \Gamma_i \boldsymbol{\varphi}_i D_i(t). \quad (57)$$

Defining equivalent modal static forces $\mathbf{F}_i^s(t)$ as in Eq. 42

$$\begin{aligned} \mathbf{F}_i^s(t) &= \mathbf{K} \mathbf{u}_i(t) = \omega_i^2 \mathbf{M} \mathbf{u}_i(t) \\ &= \omega_i^2 (\mathbf{M} \Gamma_i \boldsymbol{\varphi}_i) D_i(t) = \mathbf{s}_i \omega_i^2 D_i(t), \end{aligned} \quad (58)$$

one can write for any dynamic modal response quantity $R_i(t)$

$$R_i(t) = R_i^s \omega_i^2 D_i(t). \quad (59)$$

In the latter R_i^s is the modal response quantity that results from static analysis of the structure under the influence of the vector $\mathbf{s}_i$ of static external forces. This clearly shows that within the realm of modal decomposition, any complicated dynamic analysis of a n -DOF structure reduces to the product of two simple steps. In the first one performs static calculations for deriving all the n different R_i^s and then multiplies with the response solutions $D_i(t)$ of the n different SDOF systems loaded by $f(t)$. The total response is evidently given by the modal summation illustrated in Eq. 41.

The above modal analysis allows the introduction of another set of quantities, named the *contribution factors* $\tilde{R}_i$. These similarly to the participation factors indicate the significance of each mode in the total response. Still, their added merit lies in the fact that they are dimensionless and relieved by the abstractness of normalization. To produce them, one needs to write Eq. 59 as

$$R_i(t) = \tilde{R}_i R^s \omega_i^2 D_i(t), \quad (60)$$

in which R^s is the total response to the vector $\mathbf{s}$ of static external forces, and $\tilde{R}_i$ is the contribution factor of the i th mode defined as

$$\tilde{R}_i = \frac{R_i^s}{R^s}. \quad (61)$$

It can easily be proved that

$$\sum_{i=1}^n \tilde{R}_i = 1, \quad (62)$$

and, hence, if all modes beyond the r first modes are truncated, the corresponding error e_r is

$$e_r = 1 - \sum_{j=1}^r \tilde{R}_j, \quad (63)$$

which is usually very small for the truncation beyond the first three or four modes.

Extensions and Miscellanea

There are a number of additional topics that were intentionally excluded from the above described backbone of modal analysis. A handful of them is further elaborated in what follows. The particular intention is not to fully capture the extensive available knowledge but rather motivate the reader to further pursue the vast capabilities and multifaceted merits associated with this unique dynamics tool.

Mode Acceleration Method

The entirety of the above approach is based on estimating modal displacements, which subsequently will combine to form the total response. This displacement-based approach that naturally acquires the characterization mode displacement method was physically shown to extend into the calculation of any response variable.

Although the mode displacement method was developed typically first, it is not the only option available. One of the most useful alternatives is the so-called mode acceleration method along with its implementation variations. In identical form, though founded on a different basis, this may also be found under the name of static correction method, and the origin of this naming will below become clear. It was first devised for an undamped system, and its main attribute is that instead of modal displacements, one can seek solutions in terms of only modal accelerations for an undamped system or in terms of modal accelerations and velocities for a damped system. A brief presentation is herein put forward following the derivations and critique proposed by Cornwell et al. (1983).

Starting from the classically damped modal equation Eq. 22d, one can rewrite it as

$$\begin{aligned} q_i(t) &= \frac{1}{\omega_i^2} \left(\frac{P_i(t)}{M_i} - \ddot{q}_i(t) - 2\xi_i \omega_i \dot{q}_i(t) \right) \\ &= \frac{P_i(t)}{K_i} - \frac{1}{\omega_i^2} \ddot{q}_i(t) - \frac{2\xi_i}{\omega_i} \dot{q}_i(t), \end{aligned} \quad (64)$$

which substituting in the modal superposition Eq. 19 yields

$$\mathbf{u}(t) = \sum_{i=1}^n \boldsymbol{\varphi}_i \left(\frac{P_i(t)}{K_i} - \frac{1}{\omega_i^2} \ddot{q}_i(t) - \frac{2\xi_i}{\omega_i} \dot{q}_i(t) \right) \quad (65a)$$

or equally

$$\begin{aligned} \mathbf{u}(t) &= \sum_{i=1}^n \boldsymbol{\varphi}_i \frac{\boldsymbol{\varphi}_i^T \mathbf{F}(t)}{K_i} \\ &\quad - \sum_{i=1}^n \boldsymbol{\varphi}_i \left(\frac{1}{\omega_i^2} \ddot{q}_i(t) + \frac{2\xi_i}{\omega_i} \dot{q}_i(t) \right). \end{aligned} \quad (65b)$$

A plausible replacement is now sought for the first term in Eq. 65b. Namely, taking into account the definition of the equivalent static displacement of the structure $\mathbf{u}^s(t)$ as $\mathbf{u}^s(t) = \mathbf{K}^{-1} \mathbf{F}(t)$, as well as the definition of the equivalent static generalized displacements $q_i^s(t)$ as $q_i^s(t) = P_i(t)/K_i$, and applying Eq. 19, one gets

$$\begin{aligned} \mathbf{K}^{-1} \mathbf{F}(t) &= \mathbf{u}^s(t) = \sum_{i=1}^n \mathbf{u}_i^s(t) \\ &= \sum_{i=1}^n \boldsymbol{\varphi}_i \frac{P_i(t)}{K_i} = \sum_{i=1}^n \boldsymbol{\varphi}_i \frac{\boldsymbol{\varphi}_i^T \mathbf{F}(t)}{K_i}. \end{aligned} \quad (66)$$

Thus, the first term of the right-hand member of Eq. 65b only accounts for the total equivalent static displacement, as shown by Eq. 66. This fact evidently transforms the total displacement solution expressed by Eq. 65b into

$$\begin{aligned} \mathbf{u}(t) &= \mathbf{K}^{-1} \mathbf{F}(t) \\ &\quad - \sum_{i=1}^n \boldsymbol{\varphi}_i \left(\frac{1}{\omega_i^2} \ddot{q}_i(t) + \frac{2\xi_i}{\omega_i} \dot{q}_i(t) \right). \end{aligned} \quad (67)$$

The latter relation gives this whole alternative solution process a unique physical meaning. To obtain the dynamic response of a structure, one needs to consider first the easy to derive equivalent static (or pseudostatic) displacement and, subsequently, fine-tune it by adding the dynamic effects as introduced by the modal acceleration and velocity responses of the n individual modes. The higher mode, which trivially translates to higher frequency, would impose a relatively faster quadratic convergence for the second term in the right-hand side of Eq. 67 (see ω_i^2 denominator). Thus, this would allow less modes to be considered when truncating for economy and practicality the full series expansion. The method actually even when modes higher than $r (\ll n)$ are discarded clearly considers partly their influence through their static function.

Evidently, for an undamped system, Eq. 67 reduces to

$$\mathbf{u}(t) = \mathbf{K}^{-1} \mathbf{F}(t) - \sum_{i=1}^n \boldsymbol{\varphi}_i \frac{1}{\omega_i^2} \ddot{q}_i(t) \text{ with } \xi_i = 0, \quad (67a)$$

where the dynamic contribution of the modal velocities has been canceled out and only remains the dynamic effect of modal accelerations, which justifies the name mode acceleration method.

It is worth noting that even for a damped system, what matters in structural analysis is the maximum displacement $\max \mathbf{u}$, which causes the maximum strain and, hence, the maximum stress, required for proportioning the structural members. As a rule of thumb, this $\max \mathbf{u}$ is taken for equal to a combination of the maximum displacements $\max \mathbf{u}_i$ of the three or four first modes of the structure, which necessitates that the corresponding synchronous modal velocities become zero, $\dot{\mathbf{u}}_i = 0$. Thus, the dynamic contribution of the modal accelerations to account for

the maximum value of the dynamic response of the damped system only remains.

The method is greatly superior in terms of numerical efficacy outperforming the conventional mode displacement method in all cases by consistently requiring reduced number of modes for accurate, similar minimal error, solutions. Further the mode acceleration solution was found to be more sensitive to damping by means that increasing uniformly the damping of all modes would lead to faster convergence rates of associated dynamic solutions on reduced modal information.

Nonlinearity

The most critical assumption for applying modal analysis lies in the validity of the superposition of modes adopted in Eq. 2. This in simple terms translates to linearity of the structural system. With nonlinear behavior, developing the pursuit for a response-independent stationary modal reference system is not straightforward. Thus, the economy in the analysis of linear structures achieved through the modal order reduction cannot be realized in the analysis of nonlinear structures. Interestingly, in most real-life cases, structures move substantially, yield, or just interact with their loading environment. In all such instances, nonlinear descriptions are needed to capture the underlying phenomena waiving the validity of most of the above analysis.

A generalized manifold-type similar concept of nonlinear normal modes (NNM) has recently developed within the nonlinear dynamics field. Yet, this should be seen by engineers as more of a mathematical intricacy rather than a practical tool credible to be used in ordinary analysis of typical high-order systems. In generic nonlinear structures (this is to distinguish from cases of linear subsystems connecting through nonlinear links), the strict approach consists of numerically integrating the n -coupled equations of motion concurrently. To this purpose the time-continuous matrix Eq. 20 is written in a variational form to enable a time-stepping approach to be used for calculating purposes. Namely, Eq. 20 changes to

$$\mathbf{M}\Delta\ddot{\mathbf{u}}_i + \mathbf{C}_i\Delta\dot{\mathbf{u}}_i + \mathbf{K}_i\Delta\mathbf{u}_i = \Delta\mathbf{F}_i, \quad (68)$$

where

$$\begin{aligned} \Delta\ddot{\mathbf{u}}_i &= \ddot{\mathbf{u}}_{i+1} - \ddot{\mathbf{u}}_i, \quad \Delta\dot{\mathbf{u}}_i = \dot{\mathbf{u}}_{i+1} - \dot{\mathbf{u}}_i, \\ \Delta\mathbf{u}_i &= \mathbf{u}_{i+1} - \mathbf{u}_i, \quad \Delta\mathbf{F}_i = \mathbf{F}_{i+1} - \mathbf{F}_i, \end{aligned} \quad (69)$$

with i representing the time-step index contrary to its earlier modal meaning, while $\mathbf{C}_i$ and $\mathbf{K}_i$ are nonlinear damping and stiffness matrices, respectively, whose elements are functions of the displacement $\mathbf{u}(t)$ and the velocity $\dot{\mathbf{u}}(t)$ and take on values depending on the considered time step. The index i would translate in terms of absolute time to $i\Delta t$, where Δt denotes the time step. Alternatively, the time index $i + 1$ can be used (i.e., this is the implicit vs the explicit method when i is used). The overall response calculation problem includes three unknowns $\ddot{\mathbf{u}}_i$, $\dot{\mathbf{u}}_i$, and $\mathbf{u}_i$ for which apart from Eq. 68 two more equations could be derived from different approximations for $\ddot{\mathbf{u}}_i$ and $\dot{\mathbf{u}}_i$. As a matter of fact, depending on these approximations, which link to an assumed variance of the $\ddot{\mathbf{u}}_i$ and/or $\dot{\mathbf{u}}_i$ variables during the time-step duration, a number of different methods have developed. The most broadly used for earthquake-related purposes is Newmark's β -method.

It is noteworthy that although methods like the latter would easily produce bounded solutions (i.e., stable, meaning results will not “blow up”), whilst the time-step Δt is accurately prescribed. As a matter of fact, this is the most important parameter for any numerical integration scheme and must be sufficiently small. A first approximation for the Δt value can come from the associated modal analysis pertaining in the linear operation regime of the structure. Namely, the highest linear mode would correspond to the lowest natural period T_n . Δt should be sufficiently smaller than this T_n value. It should be reminded that this imposes large numerical limitations and costs and that the inherent softening associated with yielding would increase T_n (on the other hand, hardening would have an adverse effect by further reducing T_n).

Frequency Domain Solutions

After bringing the structural system to its modal description equivalent, the solutions pursued whether in terms of modal displacements or in terms of modal accelerations and velocities were always expressed in the time domain. Considering the case of the classically damped system with periodic loading and focusing on the probably most significant part of the response, the forced or else for this case steady state, one may suggest some alternatives to Eqs. 17 and 25. The reason is that the Duhamel's integral that provide the steady-state time response involves the convolution operation between the applied load and the unit-impulse response function. This term tends to perplex calculations.

Without detailing proofs, the alternative representation is in the frequency domain and can easily surface when one assigns inside the SDOF a periodic loading of the form $P_i(t) = P_i^o e^{j\omega t}$, where P_i^o is a scalar amplitude and again $j = \sqrt{-1}$. Then by rearranging the generalized SDOF response becomes

$$q_i(t) = \frac{P_i^o e^{j\omega t}}{(K_i - \omega_i^2 M_i) + j\omega C_i}. \quad (70)$$

Dividing Eq. 70 with $P_i(t)$ in order to create an output over input ratio, one gets

$$\begin{aligned} H(\omega) &= \frac{q_i(t)}{P_i(t)} = \frac{\tilde{q}_i(\omega)}{\tilde{P}_i(\omega)} \\ &= \frac{1}{(K_i - \omega^2 M_i) + j\omega C_i}, \end{aligned} \quad (71)$$

where over dash stands for the Fourier transform. The $H(\omega)$ function depending only on ω is called the receptance frequency response function. If, instead of displacement response, acceleration or velocity were used for the numerator, one would have the accelerance and mobility frequency response function, respectively. $H(\omega)$ is the Fourier transform of the unit-impulse response function given in Eq. 27. Generalizing the concept for an MDOF system, this instead of a scalar becomes a matrix $\mathbf{H}(\omega)$ with components

$h_{kl}(\omega)$, denoting the ratio of displacement at position k and force at position l

$$h_{kl}(\omega) = \sum_{i=1}^n \frac{\varphi_i(k)\varphi_i(j)}{M_i(\omega_i^2 - \omega^2) + j\omega C_i}. \quad (72)$$

Subsequently the convolution in the time domain is replaced in the frequency domain from a simple product of the frequency response function with the input force.

Operational Modal Analysis

To this point the presentation was focused on the so-called direct problem, which is concerned with obtaining the dynamic response of a fully known system to a given loading. By fully known it is meant that all the necessary properties to describe its behavior through a model, mainly an FE model, are in hand. Such can be the modal properties instead of the full stiffness, damping, and mass matrices. This in fact can bring a vast simplification and data economy having merits even more exaggerated than the ones modal truncation introduced before. Indicatively, for an n -DOF system, one, instead of determining $3n^2$ matrix terms, could obtain similar results by employing only a reduced number of modal frequency, damping, and shape sets. Still, this a priori assumed knowledge is not always the case. There are many uncertainties assigned to modeling (e.g., links' behavior, foundations, damping, etc.) which can bring up substantial errors in any associated model parameters and subsequently response predictions, used either for design, assessment, or control of the structure. To deal with this significant engineering issue, a major part of modal analysis nowadays has been devoted to the so-called inverse analysis. This translates to a mapping of the measured response to the system modal characteristics, and it first appeared with the development of the space program of the USA back in the 1950s. Interestingly, although the direct problem is a single-valued one, the inverse is not. The latter brings up the need for optimizing any of the prediction/analysis routines that will eventually

produce modal parameter outputs from measured response data.

The equation-free description that follows leaves aside the very interesting and demanding experimental (including signal preprocessing) techniques devised through the years to obtain the measured response from a structure under different forms of loading. The main scope of this entry is to only refer briefly to some of the most typical available tools able to obtain modal estimates once measured data are available. The mathematical background necessary to fully explain these methods are superseding the space limitations of this entry. Thus, the reader is motivated to also direct to the very insightful and broad §4 of Maia et al. (1997) as well as to a true encyclopedia on the topic by Ljung (1999) for further studying. Excellent software can be found to practice inverse analysis, some even in freeware form, which encompasses the full information provided herein and beyond. Such availability is a true late year's addition.

Practically all useful inverse analysis methods refer to MDOF systems. For them one may have information on their structural excitation or not. Their difficulty ranges from the simple peak picking method, where one observes peaks in the frequency response functions, to much more demanding alternatives employing complex algebra (Hankel matrices, Markov parameters, etc.) together with the earlier introduced state-space formulation. Most of the MDOF methods break down the structure to a superposition of independent-uncoupled SDOF systems, making even more profound the linearity and modal decomposition demands. In general, the strict target is to fit an analytical function of the form introduced in Eq. 72 to the measured data, which are customarily transformed to frequency response functions. This fitting operation inherently involved in the process lends the name curve fitting to the concept. Depending on the specific algorithm opted for the fitting, one may get the circle fitting, rational function polynomial, or many other refined approaches along the same lines.

Alternatively, one, instead of working in the frequency domain, may work employing the

time counterpart of frequency response functions, the impulse response functions. Typically the complex exponential method is used for such fittings. A similar very widespread approach fitting free decays instead of impulse response functions is named after Ibrahim, i.e., Ibrahim time domain method. Alternatively time-based methods like the option of the eigen-realization algorithm which will recover families of systems with identical eigenvalues to the measured one or generic time series tools like the autoregressive moving average can further be employed.

In all cases there is a major parameter affecting results. This is the order of the assumed model in the identification analysis. Namely, earlier treating the direct problem, one had to decide the order to which the modal solutions were to be truncated. The order that should be decided for the number of modes to be identified here is the direct equivalent.

Summary

Although every effort was made to synoptically present all the critical points that could not be missed of any educational work addressing modal analysis, the reader may still find omissions. To this reason, the wealth of references provided throughout is an excellent resource to complement the current entry as a further reading that could cover practically every aspect relating to the subject.

To recapitulate the main attributes presented herein, a short mind map is put forward that can illustrate the simple steps involved in modal analysis when employed in practical earthquake engineering purposes. This consists of:

- Determining the structural matrices $\mathbf{K}$, $\mathbf{M}$, and $\mathbf{C}$
- Determining the modal natural frequencies ω_i and shapes $\boldsymbol{\varphi}_i$
- Computing each modal-generalized response q_i (or $\ddot{q}_i$ and $\dot{q}_i$) and turning it to modal displacement $\mathbf{u}_i$

- Calculating the total displacement vector $\mathbf{u}$ after deciding the minimum number of modes r needed for an accurate solution

Model Class Selection for Prediction Error Estimation

E. Simoen¹, C. Papadimitriou² and Geert Lombaert¹

¹Department of Civil Engineering, KU Leuven, Leuven, Belgium

²Department of Mechanical Engineering, University of Thessaly, Volos, Greece

Synonyms

Bayesian error estimation; Bayesian model class updating; Likelihood function

Definitions

Model class selection Determining the most suitable model class based on the available observed data, by applying Bayesian inference at the model class level.

Prediction error The discrepancy between the observed data and the predictions made by a numerical model. In Bayesian model updating, the likelihood function is constructed as the probability density function of the prediction error.

Introduction

In Bayesian model updating, probability density functions (PDFs) of model parameters are updated based on prior knowledge and information contained in experimental data (Beck and Katafygiotis 1998). This requires the construction of the *likelihood function*, i.e., the PDF of the experimental data, or, equivalently, the PDF of the error between model predictions and observed data. Most often, a fixed zero-mean uncorrelated Gaussian prediction error (i.e., “white noise”) is assumed or presumed given; however, in many engineering applications, the magnitude of the true prediction error is unknown. Moreover, a white noise model may

not always be appropriate, for instance, when the errors show spatial or temporal correlations or a systematic component. In such cases, one can make use of the available observed data to try and estimate (characteristics of) the prediction error, provided sufficient data are at hand. Bayesian model class selection (MCS) (Beck and Yuen 2004) constitutes one of the most effective tools to this end.

Bayesian Model Updating and Prediction Error

The objective of model updating (often also referred to as *parameter estimation*) is to calibrate unknown system properties which appear as parameters in numerical models, based on actually observed behavior of the system of interest. In Bayesian model updating, this is performed in a probabilistic uncertainty quantification framework: PDFs representing the uncertainty on the model parameters are updated through the experimental data; this procedure is described briefly below.

Uncertainty in Model Updating

In general terms, a model $\mathcal{M}_M(\boldsymbol{\theta}_M)$ belonging to the model class $\mathcal{M}_M$ provides a mapping from the parameters $\boldsymbol{\theta}_M \in \mathbb{R}^{N_M}$ to an output vector $\mathbf{G}_M(\boldsymbol{\theta}_M) \in \mathbb{R}^N$ through the transfer operator $\mathbf{G}_M$:

$$\mathcal{M}_M(\boldsymbol{\theta}_M) : \mathbb{R}^{N_M} \rightarrow \mathbb{R}^N : \boldsymbol{\theta}_M \mapsto \mathbf{G}_M(\boldsymbol{\theta}_M) \quad (1)$$

In structural engineering, the prediction model class usually involves a mechanical model such as a finite element model. The model parameters $\boldsymbol{\theta}_M$ are typically properties directly connected to (sub)structure stiffness or mass (e.g., Young's modulus, moment of inertia, mass density), material properties, or parameters describing connections and boundary conditions. The model outputs $\mathbf{G}_M(\boldsymbol{\theta}_M)$ should correspond to the observed system behavior, which can consist of directly measured structural responses (displacements, accelerations) or derived system properties such as modal data (natural frequencies, mode shapes, modal flexibilities, modal

curvatures, modal strain energies). Most often, the latter are preferred: modal data are rich in information content and can be obtained in an *operational* state of the structure, meaning that no external excitation needs to be applied or known. This also explains why, for the cases considered in this text, no input vector $\mathbf{x}$ is present in Eq. 1.

In the ideal case, with a perfect model and perfect measurements, the model output $\mathbf{G}_M(\boldsymbol{\theta}_M)$ corresponds perfectly to the true system output $\mathbf{d}$, so that $\mathbf{G}_M(\boldsymbol{\theta}_M) = \mathbf{d}$. This is the underlying assumption in deterministic parameter identification, where the objective is to determine the model parameters $\boldsymbol{\theta}_M$ for a given set of observed system outputs $\mathbf{d}$. In real applications, however, the numerical model is never capable of perfectly representing the behavior of the true physical system; in other words, a modeling error is always present. This error can be described as the discrepancy between the model predictions $\mathbf{G}_M(\boldsymbol{\theta}_M)$ and the true system output $\mathbf{d}$, i.e., $\boldsymbol{\eta}_G = \mathbf{d} - \mathbf{G}_M(\boldsymbol{\theta}_M)$.

As the true system output has to be measured and processed experimentally, the data $\mathbf{d}$ are also imperfect: they are always subject to measurement error, resulting in a discrepancy between the true system output $\mathbf{d}$ and the actually observed data $\bar{\mathbf{d}}$. This difference is defined as the measurement error $\boldsymbol{\eta}_D = \bar{\mathbf{d}} - \mathbf{d}$. Eliminating the unknown true system output $\mathbf{d}$ from the error equations and collecting both errors on the right-hand side of the equation yield

$$\bar{\mathbf{d}} - \mathbf{G}_M(\boldsymbol{\theta}_M) = \boldsymbol{\eta}_G + \boldsymbol{\eta}_D = \boldsymbol{\eta} \quad (2)$$

The sum of both errors is the difference between the model predictions and the observed quantities and is defined as the total observed prediction error $\boldsymbol{\eta}$. The above expression serves as a starting point for the Bayesian uncertainty quantification method.

Bayesian Model Updating Methodology

The general principle of Bayesian parameter estimation (Beck and Katafygiotis 1998) is that uncertainties in the model parameters

$\theta_M \in \mathbb{R}^{N_M}$ that parameterize the model class $\mathcal{M}_M$ are quantified by probability density functions (PDFs), which are updated in an inference scheme based on the available information. Measurement and modeling uncertainty are taken into account by modeling the respective errors as random variables: PDFs are appointed to η_G and η_D , which are parameterized by parameters $\theta_G \in \mathbb{R}^{N_G}$ and $\theta_D \in \mathbb{R}^{N_D}$. These parameters are added to the structural model parameters θ_M to form the general model parameter set $\theta = \{\theta_M, \theta_G, \theta_D\}^T \in \mathbb{R}^{N_\theta}$. This in fact corresponds to adding two probabilistic model classes to the structural model class $\mathcal{M}_M$ to form a *joint* model class $\mathcal{M} = \mathcal{M}_M \times \mathcal{M}_G \times \mathcal{M}_D$, parameterized by θ . This procedure of probabilistic modeling is commonly referred to as *stochastic embedding* (Beck 2010).

It is important to note that in Bayesian statistics, the *Bayesian* interpretation of probability is pertained as opposed to the classical *frequentist* interpretation. In the frequentist interpretation, the probability attributed to a random variable is seen as a measure for the long-term frequency of occurrence of that variable. The Bayesian interpretation is a subjective interpretation where probability reflects a measure of plausibility or degree of belief attributed to a variable, given the current state of information. It is clear that only the Bayesian interpretation is meaningful in the context of forming inferences on model parameters using observed data.

To express the updated probabilities of the unknown parameters θ , given some observations $\bar{\mathbf{d}}$ and a certain joint model class $\mathcal{M}$, Bayes' theorem is used:

$$p(\theta|\bar{\mathbf{d}}, \mathcal{M}) = c p(\bar{\mathbf{d}}|\theta, \mathcal{M}) p(\theta|\mathcal{M}) \quad (3)$$

where $p(\theta|\bar{\mathbf{d}}, \mathcal{M})$ is the updated or posterior PDF of the model parameters given the measured data $\bar{\mathbf{d}}$ and the assumed model class $\mathcal{M}$; c is a normalizing constant that ensures the posterior PDF integrates to one; $p(\bar{\mathbf{d}}|\theta, \mathcal{M})$ is the PDF of the observed data given the parameters θ ; and $p(\theta|\mathcal{M})$ is the initial or prior PDF of the parameters. In the following, the explicit dependence on the model class $\mathcal{M}$ is omitted in order to simplify the notations.

The prior PDF $p(\theta)$ quantifies the uncertainty associated with model parameters θ in the absence of measurement results. In many cases, the prior PDF is chosen based on engineering judgment or on computational tractability (e.g., conjugate priors (Diaconis and Ylvisaker 1979)). Except in cases where a large amount of data is at hand, the prior PDF has a significant influence on the Bayesian updating results. A wide range of methods has been developed to obtain "objective" prior PDFs based on the given prior information. One of the most commonly used approaches in this respect is the method based on the maximum entropy (ME) principle (Jaynes 1957; Soize 2008), which determines the prior PDF that, given the current state of prior information, results in maximum entropy.

The PDF of the experimental data $p(\bar{\mathbf{d}}|\theta)$ can be interpreted as a measure of how good a model succeeds in explaining the observations $\bar{\mathbf{d}}$. As this PDF reflects the likelihood of observing the data $\bar{\mathbf{d}}$ when the model is parameterized by θ , it is also referred to as the *likelihood* function $L(\theta|\bar{\mathbf{d}})$. Since the data set $\bar{\mathbf{d}}$ is fixed, this function in fact no longer represents a conditional PDF and can be denoted as $L(\theta; \bar{\mathbf{d}})$; in the following, however, the common notation of $L(\theta|\bar{\mathbf{d}})$ is pertained. The likelihood function is determined according to the total probability theorem in terms of the probabilistic models of the measurement and modeling errors:

$$p(\bar{\mathbf{d}}|\theta) \equiv L(\theta|\bar{\mathbf{d}}) = \int_{\mathbb{R}^N} p_{\bar{\mathbf{d}}}(\bar{\mathbf{d}}|\theta, \mathbf{d}) p_{\mathbf{d}}(\mathbf{d}|\theta) d\mathbf{d} \quad (4)$$

$$= \int_{\mathbb{R}^N} p_{\eta_D}(\bar{\mathbf{d}} - \mathbf{d}|\theta_D) p_{\mathbf{d}}(\mathbf{d}|\theta) d\mathbf{d} \quad (5)$$

$$= \int_{\mathbb{R}^N} p_{\eta_D}(\bar{\mathbf{d}} - \mathbf{d}|\theta_D) p_{\eta_G}(\mathbf{d} - \mathbf{G}_M(\theta_M)|\theta_G) d\mathbf{d} \quad (6)$$

where $p_{\eta_D}(\bar{\mathbf{d}} - \mathbf{d}|\theta_D)$ corresponds to the probability of obtaining a measurement error η_D , given the PDF of η_D parameterized by θ_D , and where $p_{\eta_G}(\mathbf{d} - \mathbf{G}_M(\theta_M)|\theta_G)$ represents the probability of obtaining a modeling error η_G when the PDF

of $\boldsymbol{\eta}_G$ is known and parameterized by $\boldsymbol{\theta}_G$. Here, it is implicitly assumed that the modeling error and measurement error are independent variables.

The above equations show that the likelihood function can be computed as the convolution of the PDFs of the measurement and modeling error. In most realistic applications, however, no distinction can be made between measurement and modeling error. In those cases, the likelihood function can be constructed using the probabilistic model of the total prediction error $\boldsymbol{\eta}$, parameterized by $\boldsymbol{\theta}_\eta$:

$$p(\bar{\mathbf{d}}|\boldsymbol{\theta}) \equiv L(\boldsymbol{\theta}|\bar{\mathbf{d}}) = p(\boldsymbol{\eta}|\boldsymbol{\theta}_\eta) \quad (7)$$

Even though the likelihood function has a significant influence on the model updating results, its construction has received much less attention than the construction of the prior PDF. This is mainly due to the fact that most often very little or no information is at hand regarding the characteristics of the error(s); only in selected cases, a realistic estimate can be made concerning the probabilistic model representing the prediction error, for instance, based on the analysis of measurement results. Most often, it is simply assumed that the probabilistic model of the prediction error is known and fixed, so that the parameter set reduces to $\boldsymbol{\theta} = \{\boldsymbol{\theta}_M\} \in \mathbb{R}^{N_M}$.

In structural mechanics applications, an uncorrelated zero-mean Gaussian model (i.e., “white noise”) with a fixed and constant variance is typically selected to represent the prediction error. However, this common assumption is not necessarily justified or realistic. For instance, in most practical applications, the magnitude (or variance) of the errors is not (precisely) known. Moreover, a white noise model might not be appropriate to represent the true prediction error, as significant spatial or temporal correlations between the modeling error components are often likely to be present. Consider, for instance, the case where mode shapes need to be predicted along a densely populated sensor grid. Then, it can be expected that the modeling errors for two nearby mode shape components are related. In the case where time-domain data are employed,

it can similarly be suspected that modeling errors at consecutive time steps are correlated at high sampling frequencies. Besides correlations, the prediction error can show a systematic component, e.g., due to incorrect modeling assumptions or inexact measurement equipment or setup, which means assuming a zero-mean error is also not always realistic.

In order to avoid incorrect or unsuitable assumptions and thereby influencing the Bayesian updating results in an unfounded way, one can make use of the available observed data to try and estimate (characteristics of) the prediction error, for instance, using Bayesian model class selection.

Bayesian Model Class Selection

Bayesian inference can be applied at model class level to assess the plausibility of several alternative model classes based on the available observations $\bar{\mathbf{d}}$; this is referred to as Bayesian model class selection or MCS (Beck and Yuen 2004; Yuen 2010). The set of alternative model classes commonly concern (mechanical) prediction model classes $\mathcal{M}_M$, but here the method will be used to distinguish between alternative probabilistic prediction error models $\mathcal{M}_\eta$. The following, however, is elaborated for a set of general model classes $\mathcal{M}_i$.

Suppose there is a set $\mathcal{M}$ of N_C candidate model classes $\mathcal{M}_i$:

$$\mathcal{M} = \{\mathcal{M}_i\} \quad \text{where } i = 1, \dots, N_C \quad (8)$$

Then, the posterior probability of each model class $\mathcal{M}_i$ is given by Bayes’ theorem as

$$P(\mathcal{M}_i|\bar{\mathbf{d}}, \mathcal{M}) = \frac{p(\bar{\mathbf{d}}|\mathcal{M}_i)P(\mathcal{M}_i|\mathcal{M})}{p(\bar{\mathbf{d}}|\mathcal{M})} \quad (9)$$

where $P(\mathcal{M}_i|\mathcal{M})$ is the prior probability of each model class $\mathcal{M}_i$ (e.g., taken equal to $1/N_C$ when the model classes are considered equally plausible a priori), where usually the sum of all prior probabilities over all model classes is taken to be equal to 1.

The term $p(\bar{\mathbf{d}}|\mathcal{M}_i)$ in the numerator on the right-hand side of Eq. 9 is the *evidence* (sometimes also referred to as the *model class likelihood*) for the model class $\mathcal{M}_i$ provided by the data $\bar{\mathbf{d}}$. The evidence, hereafter denoted with ϵ_i , is a very important quantity in Bayesian model class selection and can be determined based on the law of total probability as

$$\epsilon_i = p(\bar{\mathbf{d}}|\mathcal{M}_i) = \int_{D_i} p(\bar{\mathbf{d}}|\boldsymbol{\theta}_i, \mathcal{M}_i) p(\boldsymbol{\theta}_i|\mathcal{M}_i) d\boldsymbol{\theta}_i \quad (10)$$

where $\boldsymbol{\theta}_i$ is the parameter vector in a parameter space D_i that defines each model in $\mathcal{M}_i$. By definition, the evidence ϵ_i gives the probability of the data according to model class $\mathcal{M}_i$. Following Eq. 10, it is determined as the weighted average of the probability of the data according to each model in the model class $\mathcal{M}_i$, where the weights are equal to the prior probability of the parameter values corresponding to each model. In fact, the evidence is equal to the a priori expected value of the likelihood. Note that it is also equal to the reciprocal of the normalizing constant c in the Bayes' theorem described by Eq. 3.

The denominator in Eq. 9, $p(\bar{\mathbf{d}}|\mathcal{M})$, is the probability of the data according to all model classes in $\mathcal{M}$ and is determined by applying the law of total probability as

$$p(\bar{\mathbf{d}}|\mathcal{M}) = \sum_{i=1}^{N_c} p(\bar{\mathbf{d}}|\mathcal{M}_i) P(\mathcal{M}_i|\mathcal{M}) \quad (11)$$

As this value is a constant, it is clear that in order to establish the most probable model class, the numerator term $p(\bar{\mathbf{d}}|\mathcal{M}_i)P(\mathcal{M}_i|\mathcal{M}) = \epsilon_i P(\mathcal{M}_i|\mathcal{M})$ in Eq. 9 has to be maximized with respect to i . Usually, the process of model class selection consists of determining the posterior probabilities of all model classes in the set $\mathcal{M}$ and ranking them accordingly, where the best model class is the one that results in the highest value of the quantity $\epsilon_i P(\mathcal{M}_i|\mathcal{M})$. Since most often equal prior model class probabilities are adopted, it suffices to compute the evidence values ϵ_i for all

model classes and to rank them accordingly. Then, the most probable model class – according to the available data – corresponds to the model class with the highest evidence value.

The actual computation of the evidence values according to Eq. 10 poses a challenging problem in most practical applications, as it entails computing complex and usually high-dimensional integrals. To overcome this problem, asymptotic approximations can be applied (Papadimitriou et al. 1997; Beck 2010), or, alternatively, methods based on stochastic simulation such as MCMC sampling (Gelfand and Dey 1994; Cheung and Beck 2010) may be used.

Model Parsimony Through Bayesian MCS

In the context of model class selection, the principle of model parsimony expresses that simpler models that are reasonably consistent with the observed data are preferable to more complicated models (e.g., with more modeling parameters), even though the more complex models might result in a better data fit. In other words, the selected class of models should be able to reproduce the observed system behavior closely, but should otherwise be as simple as possible. This principle of model simplicity is also often referred to as “Occam’s razor” and is pursued in MCS for two reasons: firstly, the achieved data fit improvement is in most cases only marginal, and secondly, an over-parameterized model may lead to an over-fit of the data. This often results in relatively poor predictions made by the model, due to the high sensitivity of the model to small changes in the data.

Many authors have suggested adding penalty terms to the log likelihood to discourage highly parameterized model classes. However, it can be shown that applying a Bayesian inference scheme at the model class level automatically enforces model parsimony, thereby avoiding the need for ad hoc penalty terms (Beck 2009). Using Bayes’ theorem and the fact that the posterior PDF integrates to one, the logarithm of the evidence in Eq. 10 can be reformulated and expanded for a general model class $\mathcal{M}$ as

$$\begin{aligned} \log \epsilon &= \log p(\bar{\mathbf{d}}|\mathcal{M}) = \mathbb{E}\{\log p(\bar{\mathbf{d}}|\boldsymbol{\theta}, \mathcal{M})\}_{\text{po}} \\ &\quad - \mathbb{E}\left\{\log \frac{p(\boldsymbol{\theta}|\bar{\mathbf{d}}, \mathcal{M})}{p(\boldsymbol{\theta}|\mathcal{M})}\right\}_{\text{po}} \end{aligned} \quad (12)$$

The first term in the above log evidence expression is the posterior mean value of the log likelihood function, termed $\log \epsilon_{\text{data}}$, which gives a measure for the average data fit for the model class $\mathcal{M}$. It is easily verified that the second term equals the Kullback–Leibler divergence D_{KL} between the prior and the posterior PDF. This term gives a measure for the difference between the prior and posterior PDF: it can be interpreted as a measure for the information that is gained from the observations $\bar{\mathbf{d}}$. It can be shown that this term is nonnegative and increases with the number of model parameters in the model class (Beck and Yuen 2004; Beck 2007); therefore, this term penalizes more complex models that attempt to extract more information from the data, thus eliminating the need for ad hoc penalty terms. In the following, the negative of this term is denoted as the Occam term $\log \epsilon_{\text{occam}}$, as it enforces the Occam simplicity principle. As such, the log evidence can be rewritten as

$$\log \epsilon = \log \epsilon_{\text{data}} + \log \epsilon_{\text{occam}} \quad (13)$$

where

$$\log \epsilon_{\text{data}} = \mathbb{E}\{\log p(\bar{\mathbf{d}}|\boldsymbol{\theta}, \mathcal{M})\}_{\text{po}} \quad (14)$$

$$\log \epsilon_{\text{occam}} = -\mathbb{E}\left\{\log \frac{p(\boldsymbol{\theta}|\bar{\mathbf{d}}, \mathcal{M})}{p(\boldsymbol{\theta}|\mathcal{M})}\right\}_{\text{po}} \quad (15)$$

Thereby, it is shown that the log evidence consists of a data fit term and a term which provides a penalty for more complex models that attempt to extract more information from the data. In other words, by applying the Bayesian inference scheme for model class selection, an explicit trade-off is made between the data fit of the model class and its complexity, without introducing ad hoc concepts.

Application: Estimation of Prediction Error Correlation Model Class

This example treats a common application of model updating in structural mechanics, namely, vibration-based structural health monitoring (SHM). In this technique, modal data extracted from vibration experiments are used to update stiffness values along a structure; as such, structural damage (i.e., loss in stiffness) can be identified, located, and quantified. In this context, Bayesian model updating provides an effective tool to assess the influence of measurement and modeling error on the SHM results.

The practical application of the prediction error estimation procedure explained above is demonstrated in a small-scale example, where a vibration test on a damaged reinforced concrete (RC) beam is simulated. This is done by modeling the beam using a detailed 3D FE model consisting of 5250 volume elements (Fig. 1) where the steel reinforcement is taken into account through an adapted material density. Structural damage is simulated by reducing the Young's modulus of a small area around one third of the length of the beam to 18.75 GPa; the rest of the beam is appointed a stiffness modulus of 37.5 GPa.

The simulated modal data consists of the first four bending modes $\bar{\boldsymbol{\phi}}_r \in \mathbb{R}^{N_s}$ at N_s degrees of freedom (DOFs) or sensors and their associated natural frequencies $\bar{f}_r$ with eigenvalues

Model Class Selection for Prediction Error Estimation, Fig. 1 3D solid FE model of the RC beam; the area with reduced stiffness is shown in red

Model Class Selection for Prediction Error Estimation,

Fig. 2 Simulated mode shapes $\bar{\phi}_r$ at $N_s = 31$ sensors and corresponding natural frequencies $\bar{f}_r = \sqrt{\bar{\lambda}}/2\pi$

$\bar{\lambda}_r = (2\pi\bar{f}_r)^2$, where free-free boundary conditions are adopted in the 3D model. To simulate a measurement error, an uncorrelated zero-mean Gaussian error with a standard deviation of 0.1 % is superimposed on these modal data. In order to assess the influence of the sensor density, three sensor configurations are considered, with $N_s = 6, 31$, and 151 equidistant sensors, and where a denser configuration includes the previous one. The final simulated experimental data set $\bar{\mathbf{d}} = \{\bar{\lambda}_1, \dots, \bar{\lambda}_4, \bar{\phi}_1^T, \dots, \bar{\phi}_4^T\}^T$ for 31 sensors is shown in Fig. 2.

The model of the RC beam that will be updated using a Bayesian inference approach is a 2D finite element model which consists of 150 beam elements and 151 nodes, with two DOFs per node, resulting in a total of $N_d = 302$ DOFs in the FE model. This prediction model is parameterized by a single parameter θ_M representing the Young's modulus of the damaged region of elements at around one third of the length of the beam. It is expected that this model combined with the simulated data will lead to prediction errors that are correlated in space; the objective is therefore to effectively account for these correlations through the proposed Bayesian MCS approach.

A zero-mean Gaussian prediction error is adopted so that $\boldsymbol{\eta} \sim \mathcal{N}(0, \Sigma_\eta)$, where it is assumed that the eigenvalue errors $\eta_{\lambda,r} = \bar{\lambda}_r - \lambda_r(\theta_M)$ are independent from the mode shape errors $\boldsymbol{\eta}_{\phi,r} = \bar{\phi}_r - \phi_r(\theta_M)$, meaning that the covariance matrix Σ_η can be constructed as

$\Sigma_\eta = \text{blkdiag}(\Sigma_\lambda, \Sigma_\phi)$. The eigenvalue covariance matrix is assumed to be diagonal and parameterized as $\Sigma_\lambda = \theta_\lambda^2 \text{diag}(\bar{\lambda}_1^2, \dots, \bar{\lambda}_4^2)$. For the mode shapes, it is suspected that the correlation length scale depends on the considered mode; therefore, it is assumed that the covariance matrix for the mode shape components can be constructed as the block diagonal matrix of 4 individual covariance matrices: $\Sigma_\phi = \text{blkdiag}(\Sigma_\phi^1, \dots, \Sigma_\phi^4)$.

Because the spatial correlation structure is unknown, a set of three alternative prediction error model classes is determined for Σ_ϕ : an uncorrelated model class A, a model class B with an exponential correlation function, and a model class C with an exponentially damped cosine correlation function. Each of these model classes is parameterized by a number of prediction error parameters as follows:

$$\Sigma_\phi^{A,r} = (\theta_{\phi,1}^{A,r})^2 \mathbf{I}_{N_s} \quad (16)$$

$$[\Sigma_\phi^{B,r}]_{ij} = (\theta_{\phi,1}^{B,r})^2 \exp\left(-\frac{\tau_{ij}}{\theta_{\phi,2}^{B,r}}\right) \quad (17)$$

$$[\Sigma_\phi^{C,r}]_{ij} = (\theta_{\phi,1}^{C,r})^2 \exp\left(-\frac{\tau_{ij}}{\theta_{\phi,2}^{C,r}}\right) \cos(\theta_{\phi,3}^{C,r} \tau_{ij}) \quad (18)$$

where τ_{ij} represents the distance between sensors i and j . These correlation models of increasing

Model Class Selection for Prediction Error Estimation,

Fig. 3 Illustration of the three employed correlation models

Model Class Selection for Prediction Error Estimation, Fig. 4 Log data fit values $\log \epsilon_{data}$ and log Occam values $\log \epsilon_{occam}$ for 6, 31, and 151 sensors

complexity (i.e., with more parameters) are illustrated in Fig. 3.

Based on the ME principle, gamma-distributed prior PDFs are assumed for all parameters (Soize 2003), and the Bayesian updating scheme is performed for all three alternative model classes using Markov Chain Monte Carlo

(MCMC) sampling where a Metropolis–Hastings sampling algorithm is used to obtain 50,000 samples of the posterior PDF. The evidence values are computed using asymptotic expressions (Simoen et al. 2013) and are shown in Fig. 4 for the three sensor configurations. Several observations can be made. Firstly, the log Occam value

clearly increases in absolute value as the model class complexity increases, confirming the statements made above regarding model parsimony. Secondly, for a low number of sensors, the uncorrelated model class is selected, indicating that correlation only becomes important for relatively dense sensor grids. However, as the number of sensors increases, the uncorrelated model class is clearly rejected, and the cosine correlation model class is eventually distinctly preferred.

The PDFs of the parameters characterizing this correlation model are estimated as well as the PDF of the stiffness parameter θ_M . For 151 sensors (and the selected cosine prediction error model class), a posterior mean value of $\mu(\theta_M) = 18.95$ GPa is found, with a standard deviation of $\sigma(\theta_M) = 0.80$ GPa.

This application shows that the Bayesian MCS approach can effectively be used to estimate a suitable correlation structure. Moreover, the MCS approach can also be applied to distinguish between different types of prediction error models (e.g., Gaussian vs. non-Gaussian) or between alternative descriptions for systematic prediction errors.

Summary

This reference entry describes the use of Bayesian model class selection to determine, among a set of possible model classes, the prediction error model class most suited for Bayesian model updating, according to the available experimental data. It is demonstrated that, provided sufficient information is available, the Bayesian MCS approach is an effective tool to this end, ensuring a more realistic joint structural-probabilistic model and corresponding Bayesian model updating results.

Introduction

Multiple forms of uncertainty exist in the prediction of a system response through the use of any type of modeling process. These uncertainties can be thought of presenting in one of three forms: parametric, predictive, and model-form uncertainty (Kennedy and O'Hagan 2001). The first of these three forms, parametric uncertainty, refers to the natural variability present within any input parameter, parameter in which a given model is reliant for predicting the response of interest. The latter two forms of uncertainty, predictive and model-form uncertainty, refer to the natural variability present within the modeling process itself. Uncertainty quantification work in the literature has primarily focused on the quantification of parametric uncertainty through the exploration, adaptation, and application of multiple approaches and methodologies. However, the majority of these approaches and methodologies fail to account for the presence of uncertainties that arise as a result of the modeling process.

Multiple models often arise as possibilities for representing the same physical situation when the solution approach for solving an engineering

problem utilizes physics-based simulations. This is often a result of differing assumptions on governing physics, physical representation of boundary or loading conditions, or solution approaches. The availability of multiple models in simulating a given physical scenario can also result from the use of various modeling packages utilizing various fidelities or even operating on differing assumptions and/or mesh sizes within the same fidelity level. In very rare situations, the phenomena being modeled have been explored extensively and are well enough understood that a "best" model can emerge from the set of possible models, where in this work the term "best" model refers to the model that most accurately represents the true physical scenario being modeled. However, in most physical scenarios in which multiple sets of differing, complex physics can couple in various ways, there exists uncertainty in the selection of this "best" model as a result of a lack of knowledge of the true physics governing the physical scenario. As a result of this uncertainty, a single "best" model will not emerge from the model set, and thus, multiple models operating on assumptions of differing physics can produce inconsistent results for the prediction of the same physical problem. Therefore, in order to completely quantify the uncertainty present in the modeling process, it is necessary to not only quantify parametric uncertainties, but also the uncertainty inherent in selecting the "best" model – the model-form uncertainty.

Multiple approaches for the quantification of model-form uncertainties are presented, discussed, and applied to a nonlinear transient concrete creep engineering problem. This entry presents the application bounds of each approach such as requirements on the availability of experimental data and whether or not the approach can account for probabilistic model predictions – predictions including the quantification of parametric and/or predictive uncertainties. These approaches include the traditional adjustment factor approaches, probabilistic adjustment factor approach (an adaptation of the prior), and the Bayesian model averaging (BMA) approach.

Uncertainty in Modeling Process

The process involved in modeling a physical scenario requires the construction of a mathematical model which entails discretization of the physical scenario as well as making assumptions on the physics governing the true scenario. It is however, often beyond the capability of the designer to fully understand the true engineering problem at hand and thus capture the full complexity and all aspects of the physical scenario. Therefore, as a result of the assumptions made during development of physics-based models, discrepancy inevitably exists between the physical scenario being modeled and the prediction of the response by the computational model. This discrepancy is referred to as the predictive uncertainty of a particular model (Droguett and Mosleh 2008), and is unique to each individual model within a set of models considered for predicting a system response.

As mentioned previously, in the solution of an engineering problem, it is common practice for multiple models to be constructed for the purpose of representing the same physical scenario. Such examples include models of varying fidelities, such as assumptions on linear, quasilinear, or nonlinearity within a model, or models that account for complex phenomenon or boundary conditions in different manners, using different simplification techniques. As a result, the predictions of each of these models, for the particular output of interest, can be different from one another. Guedes-Soares states that in situations where multiple models yield different responses, that there can exist only one correct model (Soares 1997). However, as stated earlier, it is often beyond the capability of the designer to select the “best” model within the design space, or even a subset of the design space, and arises as a result of the inability to completely understand the full complexity of the physics governing the problem. As is the case in many engineering problems, due to the physical complexity and multidisciplinary interactions, a correct model will often not exist, instead one merely seeks to identify the “best” model among the model set. For reasons mentioned above, there exists uncertainty in the selection of this “best” model.

This uncertainty in the identification of the model most accurately predicting the correct outcome is referred to as model-form uncertainty (Zhang and Mahadevan 2000).

The definition of input parameters to each model within a model set, such as dimensions, material properties, environmental conditions, or modeling constants, are often defined as being deterministic. However, in nature, the parameters are rarely deterministic, or seldom able to be accurately represented as deterministic values, within the true physical scenario. As a result of this fact, there exists a third type of uncertainty in the modeling process – parametric uncertainty – which refers to the natural variability present in the values of parameters that a mathematical model is dependent upon (Droguett and Mosleh 2008). Parametric uncertainties are often classified as either aleatory or epistemic uncertainty, dependent upon the degree of information known in regards to the form of their uncertainty (Paté-Cornell 1996). Aleatory uncertainty refers to the form of uncertainty that arises from the natural unpredictable variation in the performance of a system (Hacking 1984), and can often be represented through distribution functions of a parameter’s variability. Epistemic uncertainty, on the other hand, is defined as uncertainty due to a lack of knowledge regarding the performance of a system that can, in theory, be reduced through the introduction of additional data or information (Chernoff and Moses 2012).

All of the aforementioned uncertainties are present in nearly every physics-based modeling problem. A general representation for the modeling of an output of interest, y , is given in Eq. 1. As can be seen, this output of interest is a function of three terms: $\tilde{f}_k$, $\bar{x}_i$, and $\hat{e}_k$.

$$y = \tilde{f}_k(\bar{x}_i) + \hat{e}_k \quad (1)$$

Here, $\tilde{f}_k$ represents the result/prediction obtained using model k , to the set of input parameters, $\bar{x}_i$. The second term, $\hat{e}_k$, represents the discrepancy between the result/prediction obtained from model k , and the true physical value of the output of interest. The selection of the appropriate model, $\tilde{f}_k(\bar{x}_i)$, given this

Model-Form Uncertainty Quantification for Structural Design,
Fig. 1 Modeling uncertainty breakdown

representation of a modeling problem, is representative of the inherent model-form uncertainty whereas, the variation in $\tilde{f}_k(\bar{x}_i)$ due to the uncertainty present in the set of input parameters, $\bar{x}_i$, is representative of parametric uncertainty. Finally, the determination of a discrepancy between response/prediction of model k and the true physical value of the output of interest, $\hat{\epsilon}_k$, is representative of the predictive uncertainty present in model k . The breakdown of these three distinct types of uncertainty is demonstrated in Fig. 1.

Bayes' Theorem for Quantifying Model Probability

The first step for quantifying model-form uncertainty is to define model probabilities. Model probability is defined as the degree of belief that a model is the best approximating model from within a model set (Park et al. 2010). Original model probabilities can be assigned on one of two different concepts. Either expert opinion, if available, can be used to assign model probabilities based upon some prior knowledge of each model within the model set, or the more likely basis is to assign these probabilities based upon a uniform distribution of the probabilities assigned to each model within the model set. In the case of the uniformly distributed model probabilities where there exists K models within the model set, each model is assigned a probability of $\Pr(M_k) = 1/K$. Note that the sum of model probabilities, as shown in Eq. 2, for a model set, must be equal to 1.

$$\sum_{k=1}^K \Pr(M_k) = 1, \quad k = 1, 2, \dots, K \quad (2)$$

In the event that experimental data is available, Bayes' theorem can then be used to update these original (prior) probabilities into posterior probabilities. Applying Eq. 3 updates the model probability of model k .

$$\Pr(M_k|D) = \frac{\Pr(D|M_k)\Pr(M_k)}{\sum_{k=1}^K \Pr(D|M_k)\Pr(M_k)} \quad (3)$$

In Eq. 3, $\Pr(D|M_k)$, which is broadly known as $L(M_k|D)$, is called the likelihood of model M_k given experimental data D , or the likeliness that model M_k will predict the known data D , because the first argument D is known, while the second argument M_k is not held constant (Robert 2007). The numerical value of the likelihood, $\Pr(D|M_k)$, is not needed in the uncertainty quantification process; however, it is of importance in the evaluation of model probabilities given experimental data. Note that the denominator in Eq. 3 is common to all models, and this model likelihood value is calculated using Eq. 4 as shown by Park et al. in (Park et al. 2010).

$$\Pr(D|M_k) = \left(\frac{1}{2\pi(\hat{\sigma})_{mle}^2} \right)^{N/2} \exp\left(-\frac{N}{2}\right) \quad (4)$$

Model likelihood then becomes a function of the maximum likelihood estimator, $(\hat{\sigma})_{mle}^2$, a

measure of the variation within model k , as calculated in Eq. 5, where N in Eqs. 4 and 5 represents the number of experimental data points available for calculating the error term, ϵ . This maximum likelihood estimator provides an estimate for the model's variance based upon given experimental data in which the error term is the difference between the given experimental data point i and the prediction for that data point from model k . In Eq. 5 this error term is squared so as to eliminate the possibility of a positive and negative error canceling each other out.

$$(\hat{\sigma})_{mle}^2 = \frac{\sum_{i=1}^N \epsilon_{k,i}^2}{N} \quad (5)$$

Model-Form Uncertainty Quantification Techniques

Many methods for the quantification of model-form uncertainty have recently arisen within the literature. Each one of these methods exhibit unique advantages and disadvantages. Original work in model-form uncertainty quantification gave birth to methods requiring the presence of experimental data, such as Bayesian model averaging which requires the presence of experimental data in order to develop a maximum likelihood estimator of variance within a model prediction as is used in updating model probabilities through Bayes' theorem. Riley and Grandhi quantified the model-form and predictive uncertainty in the calculation of the flutter velocity of the AGARD 445.6 wing using BMA in (Riley and Grandhi 2011b). Other methods requiring the availability of experimental data include the methods of Continuous Model Expansion explored by Draper, which showed a reliance on experimental data points, as well as difficulty in handling asymmetric distributions of parametric uncertainties (Draper 1995), and work done recently by Allaire and Willcox, which require a maximum entropy representation of the modeling uncertainty, an extra step that could be cost intensive for a high simulation-cost model (Allaire and Willcox 2010). As previously mentioned, the common thread among these three methods is the

dependence on the availability of experimental data. The adjustment factor approach, however, was demonstrated by Mosleh and Apostolakis as a possible method for model-form uncertainty quantification which operates on the utilization of expert opinion to assign model probabilities in the absence of empirical data (Mosleh and Apostolakis 1986). Riley and Grandhi present an adaptation of this approach for use with nondeterministic model predictions, called the probabilistic adjustment actor approach (Riley and Grandhi 2011a). This work will explore the adjustment factor approaches, probabilistic adjustment factor approach, and the Bayesian Model Averaging approach and apply these methods to a multiphysics problem.

Additive Adjustment Factor Approach

As mentioned previously, the adjustment factor approach was first demonstrated by Mosleh and Apostolakis as a method for quantifying model-form uncertainty in the absence of experimental data by using an adaptation of Bayes' Theorem. This approach modifies the result of the "best" model-model within the model set being considered for use in solving the problem that obtains the highest model probability—by applying an adjustment factor to account for the uncertainty that exist in selection of the "best" model. The applicability of this approach to engineering problems has been well demonstrated in the literature. Zio and Apostolakis utilized an adjustment factor approach to quantify the uncertainty present in the selection of a "best" radioactive waste repository model in (Zio and Apostolakis 1996). Reinert and Apostolakis also used this approach in the assessment of risk for decision-making processes in (Reinert and Apostolakis 2006).

Multiple derivations of the adjustment factor approach exist in the literature. These derivatives all employ a similar technique of quantifying the model-form uncertainty through the use of expert opinion regarding a model's accuracy with respect to other models in the model set by assigning model probabilities, and updating those probabilities through the use of Bayes'

theorem upon the availability of experimental data. In this approach, $\Pr(M_k)$ represents the model probability assigned to model k . Recall that this model probability is the probability that model k is the “best” model among model set M being considered, where Eq. 6 defines the model set M .

$$M = \{M_1, M_2, \dots, M_K\} \quad (6)$$

Note that model probabilities for each of the K individual models within the model set M remain bounded by the laws of probability theory. Thus, constraints are applied to the model probability values, as shown in Eq. 7.

$$\sum_{k=1}^K \Pr(M_k) = 1 \quad \text{such that} \quad 0 \leq \Pr(M_k) \leq 1 \quad (7)$$

The various derivations of the adjustment factor approach differ here, in the form of the adjustment factor being applied—used to adjust—the “best” model. In the additive adjustment factor approach, the adjusted model, y , is formed by adding an additive adjustment factor, E_a^* , to the “best” model from the model set being considered, as shown in Eq. 8.

$$y = y^* + E_a^* \quad (8)$$

This additive adjustment factor, E_a^* , is assumed to be a normally distributed factor representing the uncertainty present in the selection of the “best” model as being most accurate at predicting the true physical response. In assuming a Gaussian form for this factor, the first and second moments—expected value and variance—of the adjustment factor are calculated as shown in Eqs. 9 and 10.

$$E[E_a^*] = \sum_{k=1}^K \Pr(M_k)(y_k - y^*) \quad (9)$$

$$\text{Var}[E_a^*] = \sum_{k=1}^K \Pr(M_k)(y_k - E[y])^2 \quad (10)$$

It is important to note that use of the adjustment factor approach is reliant on models within

the model set to be deterministic; this is to say that the models cannot incorporate parametric uncertainty. Therefore, the expected value of the adjusted model, $E[y]$, is calculated as shown in Eq. 11, as the sum of the prediction of the “best” model and the expected value of the additive adjustment factor, $E[E_a^*]$, found using Eq. 9.

$$E[y] = y^* + E[E_a^*] \quad (11)$$

Similarly, due to each individual model being deterministic, the variance of the adjusted model, $\text{Var}[y]$, assumes only the variance of the additive adjustment factor, $\text{Var}[E_a^*]$, as shown in Eq. 12.

$$\text{Var}[y] = \text{Var}[E_a^*] \quad (12)$$

The first and second moments—expected value and variance—of the adjusted prediction, y , are calculated by Eqs. 11 and 12 which fully define a normal distribution representing the uncertainty inherent in the prediction of a system response as a result of model-form uncertainty.

Multiplicative Adjustment Factor

Another derivative of the adjustment factor approach is that of a multiplicative adjustment factor. In the multiplicative adjustment factor approach, the adjusted model, y , is formed by multiplying the prediction of the “best” model, y^* from the model set being considered by a multiplicative adjustment factor, E_m^* , as shown in Eq. 13.

$$y = y^* * E_m^* \quad (13)$$

This multiplicative adjustment factor, E_m^* , is assumed to be a log normally distributed factor representing the uncertainty present in the selection of the “best” model as being most accurate at predicting the true physical response. In assuming a log normally distributed form for this factor, the first and second moments—expected value and variance—of the adjustment factor are calculated as shown in Eqs. 14 and 15.

$$E[\ln(E_m^*)] = \sum_{k=1}^K \Pr(M_k)(\ln(y_k) - \ln(y^*)) \quad (14)$$

$$\text{Var}[\ln(E_m^*)] = \sum_{k=1}^K \Pr(M_k)(\ln(y_k) - E[\ln(y)])^2 \quad (15)$$

As was the case with the additive adjustment factor approach, it is important to note that use of the adjustment factor approach is reliant on models within the model set to be deterministic. Therefore, the expected value of the adjusted model, $E[\ln(y)]$, is calculated as shown in Eq. 16, as the sum of the natural logarithm of the prediction of the “best” model and the expected value of the multiplicative adjustment factor, $E[\ln(E_m^*)]$, from Eq. 14.

$$E[\ln(y)] = \ln(y^*) + E[\ln(E_m^*)] \quad (16)$$

Much like the additive adjustment factor approach, due to each individual model being deterministic, the variance of the adjusted model, $\text{Var}[\ln(y)]$, assumes only the variance of the multiplicative adjustment factor, $\text{Var}[\ln(E_m^*)]$, as shown in Eq. 17.

$$\text{Var}[\ln(y)] = \text{Var}[\ln(E_m^*)] \quad (17)$$

While these adjustment factor approaches have the benefit of being able to quantify model-form uncertainty in the absence of experimental data, they lack the ability to handle probabilistic model predictions, this is to say that the adjustment factor approach cannot quantify the model-form uncertainty present in the selection of a “best” model, from a model set, when the models within said model set contain quantified parametric uncertainty. This is a result of the assumption made during derivation of the approach that individual models are deterministic. Therefore, a rederivation of the approach, working on the assumption that individual models are probabilistic/stochastic in nature, would allow for the approach to be adapted to handle parametric uncertainty.

Probabilistic Adjustment Factor Approach

The probabilistic adjustment factor approach is an adaptation of the traditional adjustment factor approach in that it is capable of handling stochastic models, and thus parametric uncertainty. Note that this approach does not quantify the parametric uncertainty within each model of a model set, but it can handle parametrically uncertain models in its analysis (Riley and Grandhi 2011a). As with the traditional adjustment factor approach, a distribution must first be assumed for each of the individual models within the model set for derivation of the probabilistic adjustment factor approach. In general, there is no restriction on the form of this distribution; however, as was the case with the additive adjustment factor approach, this work will focus on the approach derived from assumption of a normal distribution.

The first step to quantifying model-form uncertainty through the use of the probabilistic adjustment factor approach is the same as that of the traditional adjustment factor approach. Model probabilities are applied to each individual model within the model set using either expert opinion or uniformly distributed probabilities, and then updating through the application of Bayes’ theorem given the availability of experimental data, such that constraints of Eq. 7 are satisfied. The adjusted model for the probabilistic adjustment factor approach can then be computed as shown in Eq. 18.

$$y = E[y^*] + E_{pafa}^* \quad (18)$$

Equation 18 is similar to Eq. 8 from the additive adjustment factor approach with the slight difference in the utilization of the expected value of the “best” model, $E[y^*]$, rather than the deterministic “best” model prediction. Calculating the first and second moments—expected value and variance—of the probabilistic adjustment factor is also different for this new approach, as the approach had to be rederived to handle the stochastic model set. The calculation of these

two moments can be performed using Eqs. 19 and 20.

$$E[E_{pafa}^*] = \sum_{k=1}^K \Pr(M_k)(E[y_k] - E[y^*]) \quad (19)$$

$$\text{Var}[E_{pafa}^*] = \sum_{k=1}^K \Pr(M_k)(E[y_k] - E[y])^2 \quad (20)$$

After calculating the first and second moments of the probabilistic adjustment factor, the expected value and variance of the adjusted model can then be calculated using Eqs. 21 and 22.

$$E[y] = E[y^*] + E[E_{pafa}^*] \quad (21)$$

$$\text{Var}[y] = \text{Var}[E_{pafa}^*] + \sum_{k=1}^K \Pr(M_k)(\text{Var}[y_k])^2 \quad (22)$$

As can be seen, there is only a slight difference in the formulations of the expected value equations for the traditional adjustment factor approach and the probabilistic adjustment factor approach, only in that of operating on the expected value of the “best” model prediction rather than the deterministic model prediction, as is the case for the traditional approach. The key difference in the two derivations comes in the formulation of the variance equation. The variance, shown in Eq. 22, includes the addition of the summation of weighted individual model variances—weighted by model predictions—to the variance of the adjustment factor calculated using Eq. 20, known as the between-model variance. The second term in the equation represents the variance in the adjusted model due to variances within each of the individual models—the within-model variance. Therefore, the first term in Eq. 22 can be thought of as representing the model-form uncertainty within the problem, whereas the second term represents the parametric uncertainty inherent to each model within the model set, and quantified using parametric uncertainty quantification techniques. In the event that

individual models within the model set are deterministic, do not account for parametric uncertainties, and experimental data is available, the probabilistic adjustment factor approach can still be utilized by assuming the maximum likelihood estimator of variance for each individual model to be said model’s variance in the evaluation of Eq. 22.

Bayesian Model Averaging

The Bayesian model averaging (BMA) technique is one that requires the availability of experimental data as mentioned previously; however, this technique can handle both stochastic and deterministic models. BMA is a technique for quantifying model-form uncertainty by averaging the predictions of each individual model within a model set using each model’s corresponding model probability as a weighting factor. As is the case with the previous approaches, a distribution must be assumed for the averaged model, and the individual models, if stochastic, must follow this same distribution. For the purpose of this work, each model, if stochastic, must follow a normal distribution—defined by an expected value and variance. Thus, the averaged model assumes the form of a Gaussian distribution. The expected value of the averaged model, $E[y|D]$, is calculated by Eq. 23 as the summation of the model probabilities, $\Pr(M_k|D)$, multiplied by the corresponding model’s expected value, $E[y|M_k, D]$.

$$E[y|D] = \sum_{k=1}^K \Pr(M_k|D)E[y|M_k, D] \quad (23)$$

Similarly, the equation for calculating the variance of the averaged model is shown in Eq. 24. This equation states that the variance of the averaged model, $\text{Var}[y|D]$, is the summation of the model probabilities, $\Pr(M_k|D)$, multiplied by the corresponding model’s variance, $\text{Var}[y|M_k, D]$, plus the summation of the model probabilities multiplied by the squared difference between

the corresponding model's expected value, $E[y|M_k, D]$, and the averaged model's expected value, $E[y|D]$.

$$\begin{aligned} \text{Var}[y|D] &= \sum_{k=1}^K \Pr(M_k|D) \text{Var}[y|M_k, D] \\ &+ \sum_{k=1}^K \Pr(M_k|D) (E[y|M_k, D] - E[y|D])^2 \end{aligned} \quad (24)$$

In the event that BMA is being applied to a deterministic model set, case in which uncertainties due to input parameters are not included, Eqs. 25 and 26 are used to calculate the averaged model expected value and variance. The difference in the formulation between Eqs. 23 and 25 is that the latter used the individual model deterministic predictions, y_k , rather than their expected values. The key difference in these two derivations is seen in the formulation of the equation for calculation of averaged model variance, where the first term of Eq. 24 changes by using the maximum likelihood estimator of variance, $(\hat{\sigma})_{mle}^2$ calculated using Eq. 5, in place of the individual stochastic model variances as well as substituting the individual deterministic model predictions, y_k , for the stochastic model expected values in the first term of Eq. 26, corresponding to the second term of Eq. 24 (Park and Grandhi 2011).

$$E[y|D] = \sum_{k=1}^K \Pr(M_k|D) y_k \quad (25)$$

$$\begin{aligned} \text{Var}[y|D] &= \sum_{k=1}^K \Pr(M_k|D) (y_k - E[y|D])^2 \\ &+ \sum_{k=1}^K \Pr(M_k|D) (\hat{\sigma}_k)_{mle}^2 \end{aligned} \quad (26)$$

Application

The outlined methodology is demonstrated through application to a concrete creep engineering problem. Creep is defined as the slow

deformation a solid material undergoes under the influence of sustained stresses generated by external loads over an extended period of time. The creep deformation experienced by concrete may be three or four times as large as the initial elastic deformation caused by externally applied loads. It is widely accepted that creep deformation is largely attributed to shearing forces acting on material particles which cause them to slip against each other. Water within concrete has a large influence on the amount of slip occurring between these particles as a result of the action of weakening attractive forces binding those particles. Creep in concrete is not fully understood because it involves many factors that influence the total amount of creep a specimen experiences. The factors that considerably influence concrete creep are the aggregate, cement type, water-cement ratio, member size, curing condition, temperature and relative humidity, age of loading, and stress intensity.

The aspects of the aggregate that influence creep are the volume and the material properties. The aggregate serves to restrain creep from occurring; therefore, the magnitude of creep largely depends on the quantity and properties of the aggregate added into the mixture. Creep is inversely related to the aggregate. The content and type of cement paste are also key affecters on concrete creep. This is because creep mainly occurs in the hydrated cement paste that surrounds the aggregate. The amount of cement and amount of creep are directly correlated. Type of cement affects the strength of the concrete mixture at the time of loading. Therefore, when rapid hardening cements are used, the concrete matrix stiffness is increased at the time of loading allowing for the concrete to be more resistant to creep. Water-cement ratio is also directly related to creep. Lower water content results in higher concrete strength and thus fewer pores in the mature cement. This leads to a decrease in the amount of creep. It is thought that creep deformation decreases with an increase in member size or concrete specimen which is highly related to mobility of moisture in the concrete mixture. It has been shown that curing conditions have a substantial effect on the maturity of

concrete, and thus concrete strength. Longer curing durations tend to lead to an increase in strength and consequently decrease in creep. Ambient conditions such as temperature and relative humidity are also sources that influence creep. Higher temperatures traditionally result in higher creep until a maximum is reached in the vicinity of 71 °C at which point further rise in temperature results in a decrease in creep. Humidity results in moisture within the concrete to be diffused to the ambient, thus allowing for more creep. Due to the phenomenon that concrete strength increases as it matures, age of loading has an inverse correlation with creep. Finally, it is general acceptance that the amount of creep is approximately proportional to the applied stress; however, this proportionality is only valid up to 0.2 to 0.5 times the ultimate strength.

Several mathematical models have been suggested to estimate the amount of creep in concrete. Most of the creep-prediction models developed were empirically derived based on the outcomes of experiments carried out on concrete specimens. Here, four empirical models recommended by different committees are used to predict the amount of creep that a concrete specimen experiences under a particular environment. The four creep-prediction models are the equations contained in the ACI 209 (1997) (209 1997), the AASHTO (2007) (AASHTO 2007), the CEB-FIP (1990) (CEB 1990), and the JSCE (1996) (Sakata and Shimomura 2004) design codes. For a given condition, the empirical models for predicting creep strain, given by these four codes as a function of time (number of days after onset of loading), are given in Eqs. (27–30) respectively.

$$M_1 = 1297 \cdot 10^{-1} \frac{t^{0.6}}{10 + t^{0.6}} \quad (27)$$

$$M_2 = 671 \cdot 10^{-6} \frac{t}{24.7 + t} \quad (28)$$

$$M_3 = 1527 \cdot 10^{-6} \left(\frac{t}{307.16 + t} \right)^{0.3} \quad (29)$$

$$M_4 = 1039 \cdot 10^{-6} \left(1 - \exp \left(-0.09(1.14(t + 28) - 31.8)^{0.6} \right) \right) \quad (30)$$

The transient prediction of creep strain as predicted by each of the four models is plotted in Fig. 2. As can be seen, there is some discrepancy among the four different models. Consequently, this discrepancy is the source of model-form uncertainty. The uncertainty that arises as a result of not knowing with perfect certainty the true system response and thus which model among those available is most accurate at predicting said result.

Utilizing the additive adjustment factor approach to quantify the aforementioned model-form uncertainty, model probabilities must first be assigned using expert opinion in the absence of experimental data. The model probabilities were taken to be 0.5, 0.15, 0.05, and 0.3 for models M_1 , M_2 , M_3 , and M_4 respectively. Note that this approach is only applicable to deterministic model predictions. Application of this technique at each point in the time domain is plotted in Fig. 3, where the upper and lower 95 % confidence bounds are determined using Eqs. 31 and 32 respectively.

$$95\% \text{ Upper Bound} = E(y|D) - 1.96 \sqrt{\sum_{k=1}^K \Pr(M_k|D) \sigma_k^2 + \sum_{k=1}^K \Pr(M_k|D) (f_k - E(y|D))^2} \quad (31)$$

$$95\% \text{ Lower Bound} = E(y|D) - 1.96 \sqrt{\sum_{k=1}^K \Pr(M_k|D) \sigma_k^2 + \sum_{k=1}^K \Pr(M_k|D) (f_k - E(y|D))^2} \quad (32)$$

Utilizing the multiplicative adjustment factor approach to quantify the aforementioned model-form uncertainty, model probabilities in the same manner as with the additive adjustment factor approach. Note that this approach is also only

applicable to deterministic model predictions. Application of this technique at each point in the time domain is plotted in Fig. 4. It can be seen that the latter two model-form uncertainty quantification techniques yield nearly identical results.

Utilization of the probabilistic adjustment factor approach to quantify the aforementioned model-form uncertainty is performed in a nearly identical manner as the previous two approaches.

Model probabilities defined for the previous two techniques were also applied in this approach. Note that this approach is applicable to probabilistic model predictions, thus allowing for the

incorporation of parametric or predictive uncertainties. Here, predictive uncertainties of 15, 19, 20, and 16 % of the model prediction are accounted for in models M_1 , M_2 , M_3 , and M_4 respectively. Application of this technique at each point in the time domain is plotted in Fig. 5. It can be seen that this model-form uncertainty quantification technique yields wider confidence intervals than the previous two approaches due to incorporation of predictive uncertainties.

As mentioned previously, the Bayesian model averaging technique for quantifying model-form uncertainty requires the availability of

experimental data for proper application. The data given in Table 1 contains experimental data of measured creep strain to be used in applying the Bayesian model averaging approach. This data is plotted along with the transient responses of Fig. 2 in Fig. 6. Bayes' theorem is applied using this measured data and uniformly distributed prior model probabilities (therefore each model assumes a probability of 0.25). Upon updating prior probabilities using Bayes' theorem and obtaining maximum likelihood estimators, at which point Bayesian model averaging is carried out. The transient response is plotted in Fig. 7. It can be seen that this response is not as

seamless as the adjustment factor approaches. This is a result of the fact that this approach can only be implemented at the points that experimental data is available.

Figure 8 shows the normal distribution generated by each model-form uncertainty quantification technique, at each point an experimental data point is available. The results in this figure were all applied on model probabilities updated from uniformly distributed model probabilities using Bayes' theorem. The model variances required for applying the probabilistic adjustment factor approach are assumed to be the maximum likelihood estimators found in performing Bayes' theorem. It can be seen that the additive and multiplicative adjustment factor approaches yield nearly identical results; whereas the probabilistic adjustment factor approach yields slightly different results. The Bayesian model averaging approach on the other hand yields the most conservative distribution. Note that the adjustment factor approaches can be applied under conditions necessary for the BMA approach, as shown here, but the opposite is not possible.

Summary

Model-form uncertainty arises as a result of lack of knowledge or certainty about the models available for predicting a given response. Four methodologies were presented for the quantification of model-form uncertainty in structural design. These methodologies were the additive adjustment factor, multiplicative adjustment factor, probabilistic adjustment factor, and Bayesian model averaging approaches. Limitations on these techniques include a constraint that experimental data points be available for Bayesian model averaging and that model predictions be deterministic for the additive and multiplicative adjustment factor approaches. The probabilistic adjustment factor approach, a novel derivation of the additive adjustment factor approach, can handle stochastic model predictions in contrast to that from which it was derived.

Introduction

Elastic waves are generated by forces acting at the source and affected by the response of a medium to these forces. Mathematically, they are expressed using the representation theorem (Aki and Richards 2002, Eq. 2.41):

$$u_i(\mathbf{x}, t) = \int_{-\infty}^{\infty} \iiint_V f_k(\boldsymbol{\xi}, \tau) G_{ik}(\mathbf{x}, t; \boldsymbol{\xi}, \tau) d\tau dV(\boldsymbol{\xi}), \quad (1)$$

where $u_i = u_i(\mathbf{x}, t)$ is the observed displacement field, $\mathbf{x}$ is the position vector of an observer, t is time, and Green's tensor $G_{ik} = G_{ik}(\mathbf{x}, t; \boldsymbol{\xi}, \tau)$ is the solution of the equation of motion for a point single force with time dependence of the Dirac delta function. The Green's tensor is defined as the i th component of the displacement produced by a force in the x_k direction and describes propagation effects on waves along a path from the source to a receiver. Vector $f_k = f_k(\boldsymbol{\xi}, \tau)$ is the density of the body forces acting at the source being a function of the position vector $\boldsymbol{\xi}$ and time τ at the source. The integration in Eq. 1 is over focal volume V and time τ . For simplicity, an infinite medium is assumed in Eq. 1.

Seismic waves generated at an earthquake source and propagating in the Earth have some specific properties. Firstly, the body forces associated with the earthquake source are not distributed in a volume but along a fault. Secondly, the earthquake source is not represented by single forces but rather by dipole forces. The dipole forces cause the two blocks at opposite sides of the fault to mutually move (Fig. 1a). They are described by moment tensor density $m_{kl} = m_{kl}(\boldsymbol{\xi}, \tau)$ defined along fault Σ (Fig. 1b). A substitution of single forces by dipole forces leads to modifying Eq. 1 as follows (Burridge and Knopoff 1964; Aki and Richards 2002, Eq. 3.20):

$$u_i(\mathbf{x}, t) = \int_{-\infty}^{\infty} \iint_{\Sigma} m_{kl}(\boldsymbol{\xi}, \tau) \frac{\partial}{\partial \xi_l} G_{ik}(\mathbf{x}, t; \boldsymbol{\xi}, \tau) d\tau d\Sigma(\boldsymbol{\xi}). \quad (2)$$

Moment Tensors: Decomposition and Visualization, Fig. 1 (a) Example of motion (*normal faulting*) and (b) distribution of equivalent dipole forces along fault Σ

If the size of the fault is small with respect to distance between the source and the receiver, the representation theorem can be simplified by introducing the point source approximation:

$$u_i(\mathbf{x}, t) = \int_{-\infty}^{\infty} M_{kl}(\tau) \frac{\partial}{\partial \xi_l} G_{ik}(\mathbf{x}, t; \xi, \tau) d\tau, \quad (3)$$

or simply

$$u_i = M_{kl} * G_{ik,l}, \quad (4)$$

where $M_{kl} = M_{kl}(t)$ is the seismic moment tensor

$$M_{kl} = \iint_{\Sigma} m_{kl} d\Sigma, \quad (5)$$

and symbol “*” means the time convolution. Integration in Eq. 5 is performed over fault Σ . Moment tensor $\mathbf{M}$ is a symmetric tensor describing nine couples of equivalent dipole forces which can act at the earthquakes source (Fig. 2).

It is a basic quantity evaluated for earthquakes on all scales from acoustic emissions to large devastating earthquakes (see entries “► [Long-Period Moment-Tensor Inversion: The Global CMT Project](#),” “► [Reliable Moment Tensor Inversion for Regional- to Local-Distance Earthquakes](#),” and “► [Regional Moment Tensor Review: An Example from the European–Mediterranean Region](#)”).

The most common type of the moment tensor is the double-couple (DC) source which represents the force equivalent of shear faulting on a planar fault in isotropic media. However, many studies reveal that seismic sources often display more general moment tensors with significant non-double-couple (non-DC) components (Julian et al. 1998; Miller et al. 1998; see entry “► [Non-Double-Couple Earthquakes](#)”). An explosion is an obvious example of a non-DC source, but non-DC components can also be produced by a collapse of a cavity in mines (Rudajev and Šílený 1985), by inflation or deflation of magma chambers in volcanic areas (Mori and McKee 1987), by shear faulting on a nonplanar (curved or irregular) fault, by tensile faulting induced by fluid injection when the slip vector is inclined from the fault and causes its opening (Vavryčuk 2001, 2011), or by shear faulting in anisotropic media (Kawasaki and Tanimoto 1981; Vavryčuk 2005).

Moment Tensor Decomposition

In order to identify which type of seismic source is physically represented by a retrieved moment tensor $\mathbf{M}$, the moment tensor is usually diagonalized and decomposed into some elementary parts. The first step is the decomposition into its isotropic (ISO) and deviatoric (DEV) parts:

$$\mathbf{M} = \mathbf{M}_{\text{ISO}} + \mathbf{M}_{\text{DEV}}, \quad (6)$$

where

$$\mathbf{M}_{\text{ISO}} = \frac{1}{3} \text{Tr}(\mathbf{M}) \cdot \mathbf{I}, \quad (7)$$

**Moment Tensors:
Decomposition and
Visualization, Fig. 2** Set
of nine couples of
equivalent dipole forces
forming the moment tensor

and matrix $\mathbf{I}$ is the identity matrix. The second step is the decomposition of the deviatoric part of $\mathbf{M}$. This step is more ambiguous and can be performed in many alternative ways. The deviatoric part can be decomposed into three double couples (Jost and Herrmann 1989), into major and minor double couples (Kanamori and Given 1981; Wallace 1985), into double couples with the same T axis (Wallace 1985), or into a double couple and a compensated linear vector dipole (CLVD) component (Knopoff and Randall 1970). The last decomposition into the DC and CLVD components proved to be useful for physical interpretations and became widely accepted. This decomposition was further developed and applied by Sipkin (1986), Jost and Herrmann (1989), Kuge and Lay (1994), Vavryčuk (2015), and others, and it will be treated here in detail.

Definition of ISO, CLVD, and DC

The seismic moment tensor $\mathbf{M}$ can be decomposed using eigenvalues and an orthonormal basis of eigenvectors in the following way:

$$\mathbf{M} = M_1 \mathbf{e}_1 \otimes \mathbf{e}_1 + M_2 \mathbf{e}_2 \otimes \mathbf{e}_2 + M_3 \mathbf{e}_3 \otimes \mathbf{e}_3, \quad (8)$$

where

$$M_1 \geq M_2 \geq M_3, \quad (9)$$

and vectors $\mathbf{e}_1$, $\mathbf{e}_2$, and $\mathbf{e}_3$ define the T (tension), N (intermediate or neutral), and P (pressure) axes, respectively. Symbol “ $\otimes$ ” in Eq. 8 means the dyadic product of two vectors. Two basic properties of the moment tensor are separated in Eq. 8: (1) the orientation of the source defined by three eigenvectors and (2) the type and size of the source defined by three eigenvalues of $\mathbf{M}$.

Moment Tensors: Decomposition and Visualization, Fig. 3 The ISO, DC, and CLVD⁺ base tensors of the moment tensor. The DC part is plotted in the original coordinate system associated with the fault (DC₁) and after its diagonalization (DC₂)

The eigenvalues can be represented as a point in three-dimensional (3-D) space (Riedesel and Jordan 1989):

$$\mathbf{m} = M_1 \hat{\mathbf{e}}_1 + M_2 \hat{\mathbf{e}}_2 + M_3 \hat{\mathbf{e}}_3, \quad (10)$$

where vectors $\hat{\mathbf{e}}_1$, $\hat{\mathbf{e}}_2$, and $\hat{\mathbf{e}}_3$ define the coordinate system in this space. In order to get a unique representation, the eigenvalues must be ordered according to Eq. 9. Consequently, the points representing the source type cannot cover the whole 3-D space but only its wedge called the “source-type space.” The choice of the coordinate system and the metric for parameterizing the source-type space differ for individual moment tensor decompositions.

For physical reasons, the three terms in Eq. 8 are further restructured to form isotropic (ISO), double-couple (DC), and compensated linear vector dipole (CLVD) parts (Fig. 3) in the following way (Knopoff and Randall 1970; Dziewonski et al. 1981; Sipkin 1986; Jost and Herrmann 1989):

$$\begin{aligned} \mathbf{M} &= \mathbf{M}_{\text{ISO}} + \mathbf{M}_{\text{DC}} + \mathbf{M}_{\text{CLVD}} \\ &= M_{\text{ISO}} \mathbf{E}_{\text{ISO}} + M_{\text{DC}} \mathbf{E}_{\text{DC}} + M_{\text{CLVD}} \mathbf{E}_{\text{CLVD}}, \end{aligned} \quad (11)$$

where $\mathbf{E}_{\text{ISO}}$, $\mathbf{E}_{\text{DC}}$, and $\mathbf{E}_{\text{CLVD}}$ are the ISO, DC, and CLVD elementary (base) tensors and M_{ISO} , M_{DC} , and M_{CLVD} are the ISO, DC, and CLVD moments. The base tensors read

$$\begin{aligned} \mathbf{E}_{\text{ISO}} &= \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad \mathbf{E}_{\text{DC}} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & -1 \end{bmatrix}, \\ \mathbf{E}_{\text{CLVD}}^+ &= \frac{1}{2} \begin{bmatrix} 2 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & -1 \end{bmatrix}, \quad \mathbf{E}_{\text{CLVD}}^- = \frac{1}{2} \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -2 \end{bmatrix}, \end{aligned} \quad (12)$$

where $\mathbf{E}_{\text{CLVD}}^+$ or $\mathbf{E}_{\text{CLVD}}^-$ is used if $M_1 + M_3 - 2M_2 \geq 0$ or $M_1 + M_3 - 2M_2 < 0$, respectively. Hence, the CLVD tensor is aligned along the axis with the largest magnitude deviatoric eigenvalue. The eigenvalues of the base tensors are ordered according to Eq. 9 in order to lie in the source-type space. The norm of all base tensors, calculated as the largest magnitude eigenvalue (i.e., the maximum of $|M_i|$, $i = 1, 2, 3$), is equal to 1. This condition is called the unit “spectral norm” and physically means that the maximum dipole force of the base tensors is unity (Fig. 3). Alternative alignments of the CLVD tensor and other normalizations of the base tensors are also admissible (Chapman and Leaney 2012; Tape and Tape 2012) but have less straightforward physical interpretations.

Equations 11 and 12 uniquely define values M_{ISO} , M_{DC} , and M_{CLVD} expressed as follows:

$$M_{\text{ISO}} = \frac{1}{3}(M_1 + M_2 + M_3), \quad (13)$$

$$M_{\text{CLVD}} = \frac{2}{3}(M_1 + M_3 - 2M_2), \quad (14)$$

$$M_{\text{DC}} = \frac{1}{2}(M_1 - M_3 - |M_1 + M_3 - 2M_2|), \quad (15)$$

where M_{CLVD} includes also the sign of the elementary CLVD tensor. If the elementary CLVD tensor $\mathbf{E}_{\text{CLVD}}$ is considered with its sign as in Eq. 11, then M_{CLVD} should be calculated as the absolute value of Eq. 14. Values M_{ISO} , M_{DC} , and

M_{CLVD} in Eqs. 13, 14, and 15 are usually further normalized and expressed using scalar seismic moment M and relative scale factors C_{ISO} , C_{DC} , and C_{CLVD} :

$$\begin{bmatrix} C_{\text{ISO}} \\ C_{\text{CLVD}} \\ C_{\text{DC}} \end{bmatrix} = \frac{1}{M} \begin{bmatrix} M_{\text{ISO}} \\ M_{\text{CLVD}} \\ M_{\text{DC}} \end{bmatrix}, \quad (16)$$

where M reads

$$M = |M_{\text{ISO}}| + |M_{\text{CLVD}}| + M_{\text{DC}}, \quad (17)$$

or equivalently (Bowers and Hudson 1999)

$$M = ||\mathbf{M}_{\text{ISO}}|| + ||\mathbf{M}_{\text{DEV}}||, \quad (18)$$

where $||\mathbf{M}_{\text{ISO}}||$ and $||\mathbf{M}_{\text{DEV}}||$ are the spectral norms of the isotropic and deviatoric parts of moment tensor $\mathbf{M}$, respectively. Scale factors C_{ISO} , C_{DC} , and C_{CLVD} satisfy the following equation:

$$|C_{\text{ISO}}| + |C_{\text{CLVD}}| + C_{\text{DC}} = 1. \quad (19)$$

Equations 13, 14, 15, 16, and 17 imply that C_{DC} is always positive and in the range from 0 to 1; C_{CLVD} and C_{ISO} are in the range from -1 to 1. Consequently, the decomposition of $\mathbf{M}$ can be expressed as

$$\mathbf{M} = M(C_{\text{ISO}}\mathbf{E}_{\text{ISO}} + C_{\text{DC}}\mathbf{E}_{\text{DC}} + |C_{\text{CLVD}}|\mathbf{E}_{\text{CLVD}}), \quad (20)$$

where M is the norm of $\mathbf{M}$ calculated using Eq. 17 and represents a scalar seismic moment for a general seismic source. The absolute value of the CLVD term in Eq. 20 is used because the sign of CLVD is included in the elementary tensor $\mathbf{E}_{\text{CLVD}}$.

Physical Properties of the Decomposition

The above decomposition of the moment tensor is performed in order to physically interpret a set of nine dipole forces representing a general point seismic source and to identify easily some basic types of the source in isotropic media:

- The explosion/implosion is an isotropic source, and thus, it is characterized by $C_{\text{ISO}} = \pm 1$ and by zero C_{CLVD} and C_{DC} .
- Shear faulting is represented by the double-couple force and characterized by $C_{\text{DC}} = 1$ and by zero C_{ISO} and C_{CLVD} .
- Pure tensile or compressive faulting is free of shearing and thus characterized by zero C_{DC} . However, the non-DC components contain both ISO and CLVD. The ISO and CLVD components are of the same sign: they are positive for tensile faulting but negative for compressive faulting.
- Shear-tensile (dislocation) source defined as the source, which combines both shear and tensile faulting (Vavryčuk 2001, 2011), is characterized by nonzero ISO, CLVD, and DC components. The positive values of C_{ISO} and C_{CLVD} correspond to tensile mechanisms when fault is opening during rupturing. The negative values of C_{ISO} and C_{CLVD} correspond to compressive mechanisms when a fault is closing during rupturing. The ratio between non-DC and DC components defines the angle between the slip and the fault.
- Shear faulting on a nonplanar fault is characterized generally by a nonzero C_{DC} and C_{CLVD} . The C_{ISO} is zero, because no volumetric changes are associated with this type of source.

Source-Type Plots

For physical interpretations, it is advantageous to visualize the retrieved moment tensors graphically. Double-couple components of moment tensors are displayed using the well-known “beach balls” which show orientations of the fault together with the slip vector defining the shear motion along the fault (see entry “► Earthquake Mechanism Description and Inversion”). The non-double-couple components of moment tensors are displayed in the so-called source-type plots.

All moment tensors fill a source-type space which is a wedge in the full 3-D space. The magnitude of the vector in this space is the scalar

Moment Tensors: Decomposition and Visualization,

Fig. 4 Diamond CLVD-ISO source-type plot with positions of basic types of seismic sources. The arrows indicate the range of possible positions of moment tensors for pure tensile or compressive cracks

M

moment, and its direction defines the type of the source. In order to identify the type of the source visually, it is convenient to plot all unit vectors of the source-type space in a 2-D figure using some projections. Here, three basic plots are mentioned: diamond CLVD-ISO plot (Vavryčuk 2015), Hudson's skewed diamond plot (Hudson et al. 1989), and the Riedesel-Jordan lune plot (Riedesel and Jordan 1989).

Diamond CLVD-ISO Plot

The diamond CLVD-ISO plot shows the position of the source in the CLVD-ISO coordinate system in which the DC component is represented by the color intensity (Fig. 4). Since the sum of absolute values of the CLVD and ISO cannot exceed 1, moment tensors must lie inside a diamond. A source with pure or predominant shear faulting is located at the origin of coordinates or close to it. An explosion or implosion source is located at the top or bottom vertex of the

diamond, respectively. Motion on a pure tensile or compressive crack is plotted at the margin of the diamond. Points along the CLVD axis correspond to faulting on nonplanar faults, and points in the first and third quadrants of the diamond correspond to shear-tensile sources.

For pure tensile and shear-tensile sources, the ISO/CLVD ratio depends on the elastic properties of the medium surrounding the source. In isotropic media, this ratio is (Vavryčuk 2001, 2011)

$$\frac{C_{\text{ISO}}}{C_{\text{CLVD}}} = \frac{3}{4} \left(\frac{v_P}{v_S} \right)^2 - 1. \quad (21)$$

Hence, the point representing the pure tensile faulting in Fig. 4 (black dot) can be close to $C_{\text{ISO}} = 1$ (corresponding to an explosion) for high values of v_P/v_S but also close to $C_{\text{CLVD}} = 1$ for low values of v_P/v_S . The limiting cases are

Moment Tensors: Decomposition and Visualization, Fig. 5

The Hudson's diamond τ - k plot (a, c) and the skewed diamond u - v plot (b, d). The CLVD⁻ means the reversed CLVD axis. The dots in (a, b) show a regular grid in C_{ISO} and C_{CLVD} from -1 to $+1$ with step of 0.1 . The dots in (c, d) show 3,000 sources defined by moment tensors with randomly generated eigenvalues. For scaling of the eigenvalues, see the text. Plots (c) and (d) indicate that the distribution of random sources is uniform in both projections

$$\frac{v_P}{v_S} \rightarrow \infty \text{ and } \frac{v_P}{v_S} = \frac{2}{\sqrt{3}}, \quad (22)$$

describing fluids and the lower limit of stable solids ($\lambda = -2/3 \mu$), respectively. Similar conclusions can be drawn for pure compressive faulting (see Fig. 4).

Note that the abovementioned basic types of sources cannot be located in the second or fourth quadrants of the diamond source-type plot in Fig. 4. Moment tensors located in this area indicate numerical errors of the moment tensor inversion, a more complicated source model or faulting in anisotropic media.

As mentioned above, values $C_{\text{ISO}} = \pm 1$ and $C_{\text{DC}} = 1$ correspond to an explosion/implosion and to shear faulting in isotropic media, respectively. Their physical meaning is thus straightforward. However, the moment tensor with $C_{\text{CLVD}} = 1$ does not correspond to any simple seismic source, and the presence of CLVD in moment tensors often causes confusions and poses questions whether it is necessary to introduce the CLVD. The decomposition described above indicates that the CLVD component is required to render the decomposition

mathematically complete, and the CLVD component cannot thus be avoided. Although, it has no physical meaning itself, it can be interpreted physically in combination with the ISO component as a product of tensile faulting. In the case of a pure tensile crack, the CLVD component's major dipole is aligned with the normal to the crack surface and the volume change associated with the opening crack is described by the ISO component.

Hudson's Skewed Diamond Plot

Hudson et al. (1989) introduced two source-type plots: a diamond τ - k plot which is the diamond CLVD-ISO plot described in the previous section but with the opposite direction of the CLVD axis (Fig. 5a) and a skewed diamond u - v plot (Fig. 5b). The latter plot is introduced in order to conserve the uniform probability of moment tensor eigenvalues. If eigenvalues M_1 , M_2 , and M_3 have a uniform probability distribution between -1 and $+1$ and satisfy the ordering condition (9), then all points fill uniformly the skewed diamond plot. Axis u defines the deviatoric sources and axis v connects the pure explosive and implosive sources.

The moment tensor with arbitrary (but ordered) eigenvalues M_1, M_2 , and M_3 is projected into the u - v plot using the following equations:

$$\begin{aligned} u &= -\frac{2}{3M}(M_1 + M_3 - 2M_2), \\ v &= \frac{1}{3M}(M_1 + M_2 + M_3), \end{aligned} \quad (23)$$

where M is the scalar seismic moment calculated as the spectral norm of complete moment tensor $\mathbf{M}$

$$M = \max(|M_1|, |M_2|, |M_3|). \quad (24)$$

Equation 23 is similar to Eqs. 13 and 14 in the ISO-CLVD-DC decomposition except for scaling.

Figure 5a, b show mapping of a regular grid in C_{ISO} and C_{CLVD} calculated using Eqs. 13, 14, 15, 16, and 17 into the diamond CLVD-ISO plot and into the skewed diamond u - v plot. Figure 5b shows that the CLVD-ISO grid is deformed in the first and third quadrants of the u - v plot. Figure 5c, d demonstrate that sources with randomly generated eigenvalues cover uniformly the source-type plots. The uniform probability distribution function (PDF) is produced by the Hudson's skewed diamond plot (Fig. 5d) but also for the diamond CLVD-ISO plot. In this respect, the Hudson's skewed diamond plot does not provide any particular advantage compared to the standard CLVD-ISO plot (for details, see Tape and Tape 2012; Vavryčuk 2015).

Riedesel-Jordan Plot

A completely different approach is suggested by Riedesel and Jordan (1989) who introduce a compact plot displaying both the orientation and type of source on the focal sphere. Apparently, this plot looks simple and mathematically elegant but introduces difficulties. The moment tensor is represented by a vector defined in Eq. 10, and the coordinate axes $\hat{\mathbf{e}}_1$, $\hat{\mathbf{e}}_2$, and $\hat{\mathbf{e}}_3$ are identified with the T , N , and P axes of $\mathbf{M}$: $\mathbf{e}_1$, $\mathbf{e}_2$, and $\mathbf{e}_3$ defined in Eq. 8. The vector is normalized using the Euclidean norm

$$M = \sqrt{\frac{1}{2}(M_1^2 + M_2^2 + M_3^2)} \quad (25)$$

and projected on the sphere using a lower-hemisphere equal-area projection (see Fig. 6a).

Chapman and Leaney (2012) pointed out, however, that this representation is not optimum for several reasons. Firstly, vector $\mathbf{m}$ cannot lie everywhere on the focal sphere but inside its small part called the “lune” (Tape and Tape 2012). The lune covers only one sixth of the whole sphere (see Fig. 6b). Secondly, vectors characterizing positive and negative isotropic sources (explosion and implosion) are physically quite different, but they are displayed in the same area on the focal sphere in this projection. Thirdly, analysis of uncertainties of a moment tensor solution by plotting a cluster of vectors $\mathbf{m}$ includes both effects – uncertainties in the orientation and in the source type. This is fine if the moment tensor is nondegenerate. However, difficulties arise when the moment tensor is degenerate or nearly degenerate, because small perturbations cause significant changes of eigenvectors.

Some of the mentioned difficulties can be avoided by fixing the eigenvectors and analyzing the size of clusters produced by a varying source type only. If we fix the eigenvectors in the form

$$\begin{aligned} \mathbf{e}_1 &= \left(\frac{1}{\sqrt{3}}, \frac{1}{\sqrt{6}}, \frac{1}{\sqrt{2}} \right)^T, \\ \mathbf{e}_2 &= \left(\frac{1}{\sqrt{3}}, -\frac{2}{\sqrt{6}}, 0 \right)^T, \\ \mathbf{e}_3 &= \left(\frac{1}{\sqrt{3}}, \frac{1}{\sqrt{6}}, -\frac{1}{\sqrt{2}} \right)^T, \end{aligned} \quad (26)$$

in the north-east-down coordinate system, we obtain a plot shown in Fig. 6b. This plot resembles the diamond CLVD-ISO plot (Fig. 4) but adapted to a spherical metric. The basic source types are characterized by the following unit vectors:

$$\mathbf{e}_{\text{ISO}} = \frac{1}{\sqrt{3}}(\mathbf{e}_1 + \mathbf{e}_2 + \mathbf{e}_3) = (1, 0, 0)^T, \quad (27)$$

Moment Tensors: Decomposition and Visualization, Fig. 6 Riedesel-Jordan source-type plot. (a) The original compact plot proposed by Riedesel and Jordan (1989) displaying the orientation of the moment tensor eigenvectors (P , T , and N axes), basic source types (ISO, CLVD, DC), and the position of the studied moment tensor (*red dot*). (b, c, d) A modified Riedesel-Jordan plot proposed

by Chapman and Leaney (2012). The *dashed area* in (b) shows the area of admissible positions of sources. The *dots* in (c) show a regular grid in C_{ISO} and C_{CLVD} from -1 to $+1$ with step of 0.1 . The *dots* in (d) show 3,000 sources defined by moment tensors with randomly generated eigenvalues. Plot (d) indicates that the distribution of random sources is uniform in this projection

$$\mathbf{e}_{\text{DC}} = \frac{1}{\sqrt{2}}(\mathbf{e}_1 - \mathbf{e}_3) = (0, 0, 1)^T, \quad (28)$$

$$\begin{aligned} \mathbf{e}_{\text{CLVD}}^+ &= \sqrt{\frac{2}{3}} \left(\mathbf{e}_1 - \frac{1}{2} \mathbf{e}_2 - \frac{1}{2} \mathbf{e}_3 \right) \\ &= \left(0, \frac{1}{2}, \frac{\sqrt{3}}{2} \right)^T, \end{aligned} \quad (29)$$

$$\begin{aligned} \mathbf{e}_{\text{CLVD}}^- &= \sqrt{\frac{2}{3}} \left(\frac{1}{2} \mathbf{e}_1 + \frac{1}{2} \mathbf{e}_2 - \mathbf{e}_3 \right) \\ &= \left(0, -\frac{1}{2}, \frac{\sqrt{3}}{2} \right)^T. \end{aligned} \quad (30)$$

Basic properties of the Riedesel-Jordan projection are exemplified in Fig. 6c, d. Figure 6c shows

mapping of a regular grid in C_{ISO} and C_{CLVD} calculated using Eqs. 13, 14, 15, 16, and 17, and Fig. 6d indicates that the PDF of sources with randomly distributed eigenvalues M_1 , M_2 , and M_3 is uniform. For a detailed analysis on the probability of eigenvalues in the spherical projection, see Tape and Tape (2012).

Analysis of Moment Tensor Uncertainties Using Source-Type Plots

The source-type plots are often used for assessing uncertainties of the ISO, CLVD, and DC components of moment tensors. The reason for using the source-type plots for assessing the errors is

Moment Tensors: Decomposition and Visualization, Fig. 7 Distribution of random sources displayed in three different source-type plots. (a) The diamond CLVD-ISO plot, (b) the Hudson's skewed diamond plot, and (c) the

Riedesel-Jordan plot. The *dots* show 3,000 sources defined by moment tensors with randomly generated components in the interval from -1 to $+1$. The distribution of sources is nonuniform for all three source-type plots

simple. The moment tensor is usually plotted as a cluster of acceptable solutions, and the size of the cluster reflects uncertainties of the solution. Such approach is, however, simplistic and rough because the same uncertainties produce differently large clusters in dependence of the position of the cluster. Although the source-type plots display a uniform PDF for randomly generated eigenvalues (see section “Source-Type Plots”), the behavior of moment tensor uncertainties is not simple. When uncertainties of moment tensor components are analyzed, the moment tensor is not in the diagonal form. After diagonalizing the moment tensor, the errors are projected into the errors of eigenvalues in a rather complicated way. This is demonstrated in Fig. 7. Moment tensors in this figure have all components random and distributed with a uniform probability in the interval from -1 to 1 . Nevertheless, some source types are quite rare. In particular, sources with a high explosive or implosive component are almost missing. This observation is common for all source-type plots.

More realistic sources are modeled in Fig. 8: the pure DC and ISO sources defined by tensors $\mathbf{E}_{\text{DC}}$ and $\mathbf{E}_{\text{ISO}}$ from Eq. 12 are contaminated by random noise with a uniform distribution in the interval from -0.25 to 0.25 . The noise is superimposed to all tensor components and 1,000 random moment tensors are generated. As expected, the randomly generated source tensors form clusters, but their shape is different for different projections and their size depends also

on the type of the source. For the DC source (Fig. 8, left-hand plots), the maximum PDF is in the center of the cluster which coincides with the position of the uncontaminated source. In the diamond CLVD-ISO plot and in the skewed diamond plot, the cluster is asymmetric being stretched along the CLVD axis. A more symmetric shape of the cluster is produced in the Riedesel-Jordan plot. However, the symmetry of the cluster is apparent because the CLVD and ISO axes are of different lengths. A significantly higher scatter of the CLVD components compared to the ISO components in moment tensor inversions has been observed and discussed also in Vavryčuk (2011). For the pure ISO source (Fig. 8, right-hand plots), the clusters are smaller than for the DC source, and the maximum PDF is out of the position of the uncontaminated source. This means that the ISO percentage is systematically underestimated due to errors of the inversion for highly explosive or implosive sources.

Source Tensor Decomposition

A simple classification of sources based on the moment tensor decomposition is possible in isotropic media only. In anisotropic media, the problem is more complicated. The moment tensor is affected not only by the geometry of faulting but also by the elastic properties of the focal zone. Depending on these properties, the moment tensors can take a general form with nonzero DC,

Moment Tensors: Decomposition and Visualization,

Fig. 8 Distribution of pure DC (left-hand plots) and pure explosive (right-hand plots) sources contaminated by random noise and displayed in three different source-type plots. (a, b) The diamond CLVD-ISO plot, (c, d) the Hudson's skewed diamond plot, and (e, f) the Riedesel-Jordan plot. The dots show 1,000 DC sources defined by the elementary tensor $\mathbf{E}_{DC}$ (see Eq. (12)) and contaminated by noise with a uniform distribution from -0.25 to $+0.25$. The noise is superimposed to all tensor components

CLVD, and ISO components even for simple shear faulting on a planar fault (Vavryčuk 2005). For this reason, physical interpretations of shear or tensile dislocation sources in anisotropic media should be based on the decomposition of the source tensor, which is directly related to geometry of faulting.

The source tensor $\mathbf{D}$ (also called the potency tensor) is a symmetric dyadic tensor defined as (Ben-Zion 2003; Vavryčuk 2005)

$$D_{kl} = \frac{uS}{2} (s_k n_l + s_l n_k), \quad (31)$$

where vectors $\mathbf{n}$ and $\mathbf{s}$ denote the fault normal and the direction of the slip vector, respectively, u is

the slip and S is the fault size. The relation between the source and moment tensors reads in anisotropic media (Vavryčuk 2005, his Eq. 4)

$$M_{ij} = c_{ijkl} D_{kl}, \quad (32)$$

and in isotropic media

$$M_{ij} = \lambda D_{kk} \delta_{ij} + 2\mu D_{ij}, \quad (33)$$

where c_{ijkl} is the tensor of elastic parameters and λ and μ are the Lamé's parameters. While the moment and source tensors diagonalize in anisotropic media in different systems of eigenvectors and thus their relation is complicated, the eigenvectors of the moment and source tensors are the

Moment Tensors: Decomposition and Visualization, Fig. 9 Diamond source-type plots for the shear-tensile source model in an isotropic medium characterized by various values of the v_p/v_s ratios (the values are indicated in the plot). Red dots, source tensors; black dots, moment

tensors. The dots correspond to the individual sources. The slope angle (i.e., the deviation of the slip vector from the fault) ranges from -90° (pure compressive crack) to $+90^\circ$ (pure tensile crack) in steps of 3° .

same in isotropic media and their decomposition according to formulas in section “Definition of ISO, CLVD, and DC” yields similar results.

Properties of the moment and source tensor decompositions for shear and tensile sources in isotropic and anisotropic media are illustrated in Figs. 9 and 10. Figure 9 shows the source-type plots for tensile sources with a variable slope angle (i.e., the deviation of the slip vector from the fault) situated in an isotropic medium. The plot shows that the ISO and CLVD components are linearly dependent for both moment and source tensors. For the moment tensors, the line direction depends on the v_p/v_s ratio (Fig. 9a). For the source tensors, the line is independent of the properties of the elastic medium, and the C_{ISO}/C_{CLVD} ratio is always 1/2 (Fig. 9b). The differences between the behavior of the source and moment tensors are even more visible in anisotropic media. Figure 10 indicates that the ISO and CLVD components of the moment tensors of shear faulting (Fig. 10a, black dots) or tensile faulting (Fig. 10b, black dots) may behave in a

complicated way. For example, shear faulting in anisotropic media can produce strongly non-DC moment tensors (Vavryčuk 2005). This prevents a straightforward interpretation of moment tensors in terms of the physical faulting parameters. Therefore, first, the source tensors must be calculated from moment tensors and then interpreted (Fig. 10, red dots). If elastic properties of the medium in the focal zone needed for calculating the source tensors are not known, they can be inverted from the non-DC components of the moment tensors (Vavryčuk 2004, 2011; Vavryčuk et al. 2008). Note that the retrieved medium parameters do not refer to local material properties of the fault, but to the medium surrounding the fault.

Summary

The moment tensor represents equivalent body forces of a seismic source. The forces described by the moment tensor are not the actual forces

Moment Tensors: Decomposition and Visualization, Fig. 10 Diamond source-type plots for the shear (a) and tensile (b) source models in an anisotropic medium. The black dots in (a) correspond to 500 moment tensors of shear sources with randomly oriented fault and slip. The black dots in (b) correspond to moment tensors of tensile sources with strike = 0°, dip = 20°, and rake = -90° (normal faulting). The slope angle ranges from -90° (pure

compressive crack) to +90° (pure tensile crack) in steps of 3°. The red dots in (a) and (b) show the corresponding source tensors. The medium is transversely isotropic with the following elastic parameters (in $10^9 \text{ kg m}^{-1} \text{ s}^{-2}$): $c_{11} = 58.81$, $c_{33} = 27.23$, $c_{44} = 13.23$, $c_{66} = 23.54$, and $c_{13} = 23.64$. The medium density is $2,500 \text{ kg/m}^3$. The parameters are taken from Vernik and Liu (1997) and describe the Bazhenov shale (depth of 12,507 ft)

acting at the source because the moment tensor description assumes elastic behavior of the medium and ignores nonlinear rheology at the focal area. Nevertheless, the moment tensor proved to be a useful quantity and became widely accepted in seismological practice for studying seismic sources. The moment tensor is evaluated for earthquakes on all scales from acoustic emissions to large devastating earthquakes.

In order to understand physical processes at the earthquake source, the moment tensor is commonly decomposed into double-couple (DC), isotropic (ISO), and compensated linear vector dipole (CLVD) components. High percentage of DC indicates a source with shear faulting in isotropic media, and high percentage of ISO indicates an explosive or implosive source. A combination of positive (negative) ISO and CLVD is produced by tensile (compressive) faulting. The type of the source can be visualized using the so-called source-type plots; among

them, the diamond CLVD-ISO plot, the Hudson's skewed diamond plot, and the Riedesel-Jordan lune plot are in common use. In anisotropic media, the physical interpretation of the DC, ISO, and CLVD percentages is not straightforward, and the decomposition of the moment tensor must be substituted by that of the source tensor.

Introduction

Volcanic eruptions represent a great hazard to population leaving nearby volcanoes. In order to better understand volcanic activity and thus to improve eruption forecasting, it is of primary importance to better image and monitor the structure of volcanic edifices.

In the field of ultrasonics, it has been shown both theoretically and experimentally that a random wavefield has correlations which, on average, take the form of the Green's function of the media (Weaver and Lobkis 2001). In seismology, recent studies also showed that the Green's function between pairs of seismographs can be extracted from cross-correlations of coda waves and ambient noise (Campillo 2006). Moreover, some authors used correlations of long ambient

seismic noise sequences from regional networks in order to extract and to invert Rayleigh waves to produce high-resolution seismic images of the shallow crustal layers under these networks (Shapiro et al. 2005). The first part of this entry will show how noise-based seismic imaging can be employed to image volcano interiors.

The early detection of volcanic unrest mainly relies on the monitoring of volcanic seismicity and ground deformation. Those methods provide insights into the dynamics of magma pressurization and transport. However, despite considerable effort, the precise forecasting of eruptions and their intensity has proven to be difficult. Therefore, there is a constant need for novel observational methods to obtain information about ongoing volcanic processes. Pressurized volcanic fluids (magma, water) or gases induce deformation and thus perturbations of the elastic properties of volcanic edifices. These small perturbations can be detected as changes of seismic wave properties using repetitive seismic sources (Ratdomopurbo and Poupinet 1995; Grêt et al. 2005; Wegler et al. 2006). However, none of these approaches were apt to provide a continuous monitoring of volcano elastic properties. In a pioneering work, Sens-Schoenfelder and Wegler (2006) proposed to use the repetitive waveforms of seismic noise cross-correlations to track for subsurface volcanic edifice velocity changes. In this manner, the continuous recording of ambient seismic noise allows continuous monitoring of volcano interiors. The second part of this paper will show how

noise-based seismic monitoring can be employed to monitor volcano interiors.

Noise-Based Seismic Imaging of Piton de la Fournaise Volcano

Piton de la Fournaise Volcano (PdF) is a hot spot, shield volcano located on La Réunion island in the Indian Ocean (Fig. 1). It erupted more than 30 times between 2000 and 2010. These eruptions lasted from a few hours to a few months and were associated with the emission of mainly basaltic lava with volume ranging from less than one to tens of million cubic meters (Peltier et al. 2009). The time period that is considered here (1999–2011) started and ended with two major eruptions, namely, the March 1998 eruption (60 million of cubic meter of lava emitted) and the April 2007 eruption associated to the 300 m high collapse of the main Dolomieu crater (130 million of cubic meter of lava emitted) (Staudacher et al. 2009).

Piton de la Fournaise Volcano is monitored by OVPF/IPGP volcano observatory. In 2009, in the framework of UnderVolc project (Brenguier et al. 2012), 15 new broadband seismic stations complemented the observatory seismic network that was composed of about 20 seismic stations. The intense eruptive activity together with a weak tectonic activity makes Piton de la Fournaise Volcano well suited for studies focused on the processes of magma pressurization and injection and for the development of innovative imaging and monitoring methods.

By using continuous records of ambient seismic noise from the PdF Volcano observatory short-period seismic network, Brenguier et al. (2007) were able to measure Rayleigh wave velocity dispersion curves obtained from the cross-correlations of 18 months of ambient seismic noise. The tomography of these measurements as well as the depth inversion led to a high-resolution image of the shallow structure of PdF Volcano (Fig. 2). The results show a high seismic velocity body located in the central part of the

Noise-Based Seismic Imaging and Monitoring of Volcanoes, Fig. 2 3D tomographic image of the shallow central part of Piton de la Fournaise Volcano using cross-correlations of ambient seismic noise (Breguier et al. 2007)

volcano. This body is being interpreted as a preferential zone of magma injection within the edifice. The high velocities are associated with intrusive magma slowly cooling within the surrounding effusive low velocity material. This information is crucial in order to define a more precise structural model for the volcano edifice and thus to better model and then understand the response of the volcano to magmatic activity.

Noise-Based Seismic Monitoring of Piton de la Fournaise Volcano

The approach consists in measuring very small waveform time delays in the coda of noise cross-correlations. This method is described as the so-called Moving Window Cross Spectrum (Ratdompurbo and Poupinet 1995; Clarke et al. 2011) or Coda Wave Interferometry (Snieder et al. 2002) techniques. Coda waves (late part of seismograms) are scattered waves that travel long distances and thus accumulate

time delays as a consequence of a seismic velocity change in the propagating medium. Measuring travel time perturbations in the coda thus allows detecting very small velocity changes that would not be detectable by a classical measure of first arrival time delays. The drawback of that approach is that it is difficult to estimate the travel paths of the scattered waves constituting the coda. However, recent promising results suggest it may be possible to produce refined 3D maps of small changes in a near future (Larose et al. 2010).

In a previous work Breguier et al. (2012) measured seismic velocity variations within the Piton de la Fournaise edifice from June 2010 to April 2011 following Breguier et al. (2008). Continuous seismic velocity changes as well as the daily seismicity rate are shown on Figs. 3 and 4 for two different time periods at PdF volcano. Figure 3 shows small (0.1 %) seismic velocity drops preceding eruptions at PdF volcano. On Fig. 4, the authors observe a velocity drop starting about 1 month before the 2010 October 14th eruption. The velocity decrease correlates in time with an increase of seismicity and has been interpreted as the deformation of the edifice induced by magma pressure buildup and injection. These velocity drops are interpreted as being associated with the deformation of the edifice induced by magma pressure buildup. Interestingly, seismic velocity increases during the eruption of October 2010 and after the short eruption of December 2010 indicating a possible mechanism of stress relaxation induced by the emptying of the magmatic reservoir. Furthermore, to improve the accuracy and thus time resolution of velocity measurements, Baig et al. (2009) developed a cross-correlation filtering method based on time-frequency transforms and phase coherence filtering.

Noise-based seismic velocity monitoring is thus a unique method that allows to precisely monitor volcanic activity. It must however be mentioned that other phenomena perturb seismic velocities of the rock mass such as the presence of water in the medium, temperature and barometric atmospheric pressure changes, and solid and oceanic tides. It is thus important

Noise-Based Seismic Imaging and Monitoring of Volcanoes, Fig. 3 (a) Relative velocity changes compared to extensometer (FORX) located on PdF volcano. The travel time shifts are measured in the frequency range

0.1–0.9 Hz. For details, see Brenguier et al. (2008) (b) Inter-eruptive seismicity (pre-eruptive swarms are excluded)

Noise-Based Seismic Imaging and Monitoring of Volcanoes, Fig. 4 Relative seismic velocity changes with error bars and daily seismicity rate between June 2010 and April 2011. Eruption periods are shown as gray rectangles

to correctly model these effects in order to correct them from the observed seismic velocity changes in order to extract the volcanic-related signal.

In April 2007, a major eruption occurred at Piton de la Fournaise Volcano ejecting more than 250 million cubic meters of lava and located a few kilometers east of the main active central part of the volcano. Clarke et al. (2013) observed an unusual high seismic velocity drop associated with this volcanic episode that could not be explained by the pre-eruptive edifice inflation due to magma pressure buildup as described by (Brennguier et al. 2008). Also, (Clarke et al. 2013) showed surface displacements images obtained from InSAR data inversion by J-L. Froger (OPGC, France). These results show that between March and May 2007, a widespread volcanic edifice flank movement occurred with a maximum of 1.4 m of eastward displacement. However, the timing of this movement and, in particular, its relation with the occurrence of the April 2007 eruption could not be identified by a lack of temporal resolution of the InSAR images. Clarke et al. (2013) proved using high temporal resolution seismic velocity change measurements that the strong drop of seismic velocities started at the time of a small eruption preceding the main April eruption by a few days. Inferring the association between this high seismic velocity drop and the widespread volcanic flank movement, the authors concluded that the volcanic flank movement started at the time of the small eruption preceding the main April 2007 eruption by a few days. Considering new simulation of volcanic edifice deformation from Got et al. (2013), it is likely that the small eruption preceding the main one triggered a large elastoplastic deformation of the edifice flank that released stresses and favored the horizontal migration of magma to a long distance through the April 2007 eruptive fissure. This study showed how noise-based monitoring has been used to explain the origin of the unusual April 2007 eruption at Piton de la Fournaise Volcano and that this method can also be used to detect volcanic flank movements and possible instabilities on volcanoes.

This method is now used routinely at the Piton de la Fournaise Observatory in order to improve eruption forecasting together with earthquake and deformation observations. Lecocq et al. (2013) developed an integrated package that includes all processing steps required to obtain continuous seismic velocity changes from continuous seismic records. This package is available for free at www.msnoise.org.

Summary

Ambient seismic noise continuously travels along the surface and the interiors of the Earth. These seismic waves thus carry crucial information about the medium they propagate through. When crossing volcanoes, these waves are affected by the mechanical heterogeneities of the volcanic edifice and are also perturbed during unrest periods by temporal changes of volcano interiors. Noise-based seismic imaging and monitoring allows imaging the structure and temporal evolution of volcanic edifices. In particular, it proved success in detecting very small changes of seismic velocities of volcanic edifices (0.1 %) that have been shown, on Piton de la Fournaise Volcano (La Réunion island), to be precursors of volcanic eruptions.

Non-Double-Couple Earthquakes

G. R. Foulger and Bruce R. Julian
Department of Geological Sciences, Durham
University, Durham, UK

Introduction

Non-double-couple (“non-DC”) earthquake mechanisms differ from what is expected for pure shear faulting in a homogeneous, isotropic, elastic medium. Until the mid-1980s, the DC assumption underlay nearly all seismological analysis, and was highly successful in advancing our understanding of tectonic processes and of seismology in general. In recent years, though, many earthquakes have been found that do not fit the DC model. Earthquakes that depart strongly from DC theory range in size over many orders of magnitude and occur in many environments, but are particularly common in volcanic and geothermal areas. Moreover, minor departures from the DC model are detected increasingly frequently in studies using high-quality data. These observations probably reflect departures from idealized models, caused by effects such as rock anisotropy or fault curvature.

At the same time, it has become clear that industrial activities such as oil and gas production and storage, hydrofracturing, geothermal energy exploitation, CO₂ sequestration, and waste

disposal can induce earthquakes, and that these events often have non-DC mechanisms. Induced earthquakes pose legal hazards because of their destructive potential, but they can also be beneficial, because they can be used to monitoring physical processes that accompany industrial activity.

Non-DC earthquakes are therefore important for improving our understanding of how faults and volcanoes work, perhaps leading some day to an ability to predict earthquakes and eruptions, for avoiding nuisance seismicity in connection with industrial activity, and for monitoring such activity in detail.

Non-DC earthquake mechanisms, by definition, require for their description a more general mathematical formalism than the DC model. The most widely used such formalism is the expansion of the elastodynamic field in terms of the spatial moments of the equivalent-force system (Gilbert 1970). Usually, attention is restricted to second moments, and thus to second-rank moment tensors, and moreover these tensors are usually assumed to be symmetric, so that they have six independent components (A DC has four independent components.). This restriction is not always justified, however. Sources involving net forces or torques are theoretically possible, and phenomena such as landslides and volcanic eruptions provide clear examples of them.

Because it has two extra adjustable parameters, a moment tensor can describe volume changes and general kinds of shear deformation. This increased generality allows the moment tensor to encompass physical processes such as geometrically complex faulting, tensile faulting, faulting in anisotropic media, faulting in heterogeneous media (e.g., near an interface), and polymorphic phase transformations.

The moment tensor also has an important computational property: Mathematical expressions for static and dynamic displacement fields are linear in the moment-tensor components. This property facilitates the evaluation of these fields and enormously simplifies the inverse problem of deducing source mechanisms from observations.

Representation of Earthquake Mechanisms

The Equivalent Force System

Physically, an earthquake involves a nonlinear failure process occurring within a limited region. The equivalent force system, acting in an intact (unfaulted) “model” medium, would produce the same displacement field outside the source region. Any physical source has a unique equivalent force system in a given model medium, but the converse statement is not true. Different physical processes can have identical force systems and therefore identical static and dynamic displacement fields.

The equivalent force system is all that can be deduced from observations of displacement fields, so it constitutes a phenomenological description of the source. There is a one-to-one correspondence between equivalent force systems and elastodynamic fields outside the source region, so we can, in principle at least, determine force systems from observations. On the other hand, the correspondence between force systems and physical source processes is one-to-many, so equivalent force systems (and therefore seismic and geodetic observations) cannot uniquely diagnose physical source processes.

Failure can be regarded as a sudden localized change in the constitutive relation (stress–strain law) in the Earth (Backus 1977). Before an earthquake, the stress field satisfies the equations of equilibrium. At the time of failure, a rapid change in the constitutive relation causes the stress field to change. The resulting disequilibrium causes dynamic motions that radiate elastic waves. We disregard the effect of gravity in the following discussion. In the absence of external forces, the equation of motion is

$$\rho \ddot{u}_i = \sigma_{ij,j}, \quad (1)$$

where $\rho(\mathbf{x})$ is density, $\mathbf{u}(\mathbf{x}, t)$ is the particle displacement vector, $\sigma(\mathbf{x}, t)$ is the physical stress tensor, $\mathbf{x}$ is position, and t is time. Dots indicate differentiation with respect to t , ordinary subscripts indicate Cartesian components of vectors or tensors, the subscript, j indicates

differentiation with respect to the j th Cartesian spatial coordinate x_j , and duplicated indices indicate summation. The true stress is unknown, however, so in theoretical calculations we use the stress $\mathbf{s}(\mathbf{x}, t)$, given by the constitutive law of the model medium (usually Hooke's law). If we replace σ_{ij} by s_{ij} in the equations of motion, though, we must also introduce a correction term, $\mathbf{f}(\mathbf{x}, t)$:

$$\rho \ddot{u}_i = s_{ij,j} + f_i, \quad (2)$$

$$f_i \stackrel{\text{def}}{=} (\sigma_{ij} - s_{ij})_{,j}. \quad (3)$$

This term has the form of a body-force density and is the equivalent force system of the earthquake. It differs from zero only within the source region.

Net Forces and Torques

Nearly all analyses of earthquake source mechanisms explicitly exclude net forces and torques. The equivalent forces given by Eq. 3, which arise from the imbalance between true physical stresses and those in the model, are consistent with these restrictions. The stress glut $\sigma_{ij} - s_{ij}$ is symmetric, so $\mathbf{f}$ exerts no net torque at any point. Furthermore, $\sigma_{ij} - s_{ij}$ vanishes outside the source region, so Gauss's theorem implies that the total force vanishes at each instant.

More complete analysis, however, including the effects of gravitation and mass advection, shows that Eq. 3 is based on overly restrictive assumptions and that net force and torque components are possible for realistic sources within the Earth (Takei and Kumazawa 1994). These forces and torques transfer linear and angular momentum between the source region and the rest of the Earth, with both types of momentum conserved for the entire Earth. An easily understood example is the collapse of a cavity, in which rocks fall from the ceiling to the floor. While the rocks are falling, the Earth outside the cavity experiences a net upward force, relative to the state before and after the event.

The net force component in any source is constrained by the principle of conservation of

momentum; if the source region is at rest before and after the earthquake, the total impulse of the equivalent force (its time integral) must vanish. No such requirement holds for the torque. The total torque exerted by gravitational forces need not vanish even after the earthquake. Horizontal displacement of the center of mass of the source region leads to a gravitational torque, which must be balanced by stresses on the boundary of the source and causes the radiation of elastic waves. Because gravity acts vertically, there can be no net torque about a vertical axis.

The Moment Tensor

We cannot use the equivalent force system $\mathbf{f}(\mathbf{x}, t)$ and the elastodynamic Eq. 2 to determine the displacement field for a hypothetical source. The equivalent force system itself depends on the displacement field that is being sought. Two different approaches are commonly used: (i) In the kinematic approach we assume some mathematically tractable displacement field in the source region (e.g., suddenly imposed slip, constant over a rectangular fault plane), derive the equivalent force system from Eq. 3, and solve Eq. 2 for the resulting displacement field outside the source region; and (ii) in the inverse approach, we use Eq. 2 to determine the force system $\mathbf{f}(\mathbf{x}, t)$ from the observed displacement field and compare the result with force systems predicted theoretically for hypothesized source processes. The most useful way to parameterize the force system in this approach is to use its spatial moments.

The Moment-Tensor Expansion for the Response
Given the equivalent force system $\mathbf{f}(\mathbf{x}, t)$, computing the response of the Earth is a linear problem, and its solution can be expressed as an integral over the source volume V (Aki and Richards 2002, Eq. 3.1, omitting displacement and traction discontinuities for simplicity):

$$u_i(\mathbf{x}, t) = \iiint_V G_{ij}(\mathbf{x}, \boldsymbol{\xi}, t) * f_j(\boldsymbol{\xi}, t) d^3\boldsymbol{\xi}, \quad (4)$$

where $G_{ij}(\mathbf{x}, \boldsymbol{\xi}, t)$ is the Green's function, which gives the i th component of displacement at

position $\mathbf{x}$ and time t caused by an impulsive force in the j direction applied at position ξ and time 0, and the symbol $*$ indicates temporal convolution. If we expand the Green's function in a Taylor series in the source position ξ ,

$$G_{ij}(\mathbf{x}, \xi, t) = G_{ij}(\mathbf{x}, \mathbf{0}, t) + G_{ij,k}(\mathbf{x}, \mathbf{0}, t)\xi_k + \dots, \quad (5)$$

Eq. 4 for the response becomes

$$u_i(\mathbf{x}, t) = G_{ij}(\mathbf{x}, \mathbf{0}, t) * F_j(t) + G_{ij,k}(\mathbf{x}, \mathbf{0}, t) * M_{jk}(t) + \dots, \quad (6)$$

where

$$F_j(t) \stackrel{\text{def}}{=} \iiint_V f_j(\xi, t) d^3\xi \quad (7)$$

is the total force exerted by the source and

$$M_{jk}(t) \stackrel{\text{def}}{=} \iiint_V \xi_k f_j(\xi, t) d^3\xi \quad (8)$$

is the moment tensor. If the equivalent force is derivable from a stress glut via Eq. 3, then the moment tensor is the negative of the volume integral of the stress glut:

$$M_{jk}(t) = - \iiint_V (\sigma_{ij} - s_{ij}) d^3\xi \quad (9)$$

The moment tensor is a second-rank tensor, which describes a superposition of nine elementary force systems, with each component of the tensor giving the strength (moment) of one force system. The diagonal components M_{11} , M_{22} , and M_{33} correspond to linear dipoles that exert no torque, and the off-diagonal elements M_{12} , M_{13} , M_{21} , M_{23} , M_{31} , and M_{32} correspond to force couples. It is usually assumed that the moment tensor is symmetric, ($M_{12} = M_{21}$, $M_{13} = M_{31}$, $M_{23} = M_{32}$), so that the force couples exert no net torque (see above), in which case only six moment-tensor components are independent. In this case, the off-diagonal components correspond to three pairs of force couples, each exerting no net torque ("double couples").

The magnitudes of the six (or nine) elementary force systems (the moment-tensor components) transform according to standard tensor laws under rotations of the coordinate system, so there exist many different combinations of elementary forces that are equivalent. In particular, for a symmetric (six-element) moment tensor one can always choose a coordinate system in which the force system consists of three orthogonal linear dipoles, so that the moment tensor is diagonal. In other words, a general point source can be described by three values (the principal moments) that describe its physics and three values that specify its orientation.

The moment tensor has three important properties that make it useful for representing seismic sources. (1) It makes the "forward problem" of computing theoretical seismic-wave excitation linear. A general source is represented as a weighted sum of elementary force systems, so any seismic wave is just the same weighted sum of the waves excited by the elementary sources. The linearity of the forward problem in turn makes much more tractable the inverse problem of determining source mechanisms from observations. (2) It simplifies the computation of wave excitation. By transforming the moment tensor into an appropriately oriented coordinate system, the angles defining the observation direction can be made to take on special values such as 0 and $\pi/2$. Thus radiation by the elementary sources must be computed not for a general direction, but for only a few directions for which the computation is easier. In a laterally homogeneous medium, for example, radiation must be computed for only a single azimuth. (3) The moment tensor is more general than the DC representation. It includes DCs as special cases, but has two more free parameters than a DC (six vs. four), which enable it to represent sources involving volume changes and more general types of shear.

Higher-Rank Moment Tensors

As Eq. 6 shows, "the" moment tensor described above is only one of an infinite sequence of spatial moments that appear in the expansion of the Earth's response to an earthquake. The later terms involve higher-rank moment tensors,

which contain information about the spatial and temporal distribution of failure in an earthquake, and have great potential value for studying source finiteness and rupture propagation.

Surface Sources (Faults)

A fault is a surface across which there is a discontinuity in displacement. The equivalent force distribution, $\mathbf{f}$, for a generally oriented fault in an elastic medium is, from Eq. 2,

$$f_k(\eta, t) = - \iint_A [u_i(\xi, t)] c_{ijkl} v_j \frac{\partial}{\partial \eta_l} \delta(\eta - \xi) dA, \quad (10)$$

where η is the position where the force is evaluated, ξ is the position of the element of area dA , and the integration extends over the fault surface (Aki and Richards 2002, Eq. 3.5). The unit vector normal to the fault surface is $v(\xi)$ and $[u(\xi, t)]$ is the displacement discontinuity across the fault in the direction of v . The components of the elastic modulus tensor are c_{ijkl} and $\delta(\mathbf{x})$ is the three-dimensional Dirac delta function.

Substituting the force distribution from Eq. 10 into Eq. 8 gives the moment tensor of a general fault,

$$M_{ij} = -c_{ijkl} A \overline{v_k [u_l]}, \quad (11)$$

where A is the total fault area and the overbar indicates the average value over the fault.

Shear Faults

For a planar shear fault (with normal v in the x_3 direction and displacement discontinuity $[u]$ in the x_1 direction, say, so that $v_1 = v_2 = 0$ and $[u_2] = [u_3] = 0$) in a homogeneous isotropic medium ($c_{ijkl} = \lambda \delta_{ij} \delta_{kl} + 2\mu \delta_{ik} \delta_{jl}$), Eq. 8 gives a moment tensor with two nonzero components $M_{13} = M_{31} = \mu A \bar{u}$, where $\bar{u}$ is the average slip. This corresponds to a pair of force couples, one with forces in the x_1 direction and moment arm in the x_3 direction, and the other with these directions interchanged.

We get the same DC moment tensor for a fault with normal in the x_1 direction and displacement

discontinuity in the x_3 direction. This ambiguity between “conjugate” faults is an example of the fundamental limitations on the information that can be deduced from equivalent force systems.

Tensile Faults

For a tensile fault in a homogeneous isotropic medium, with the fault lying in the x_1 - x_2 plane and opening in the x_3 direction, $v_1 = v_2 = 0$ and $[u_1] = [u_2] = 0$. Equation 8 gives a moment tensor with three non-zero components: $M_{11} = M_{22} = \lambda A \bar{u}$ and $M_{33} = (\lambda + 2\mu) A \bar{u}$, corresponding to two dipoles in the fault plane with moments of $\lambda A \bar{u}$, and a third dipole oriented normal to the fault and with a moment of $(\lambda + 2\mu) A \bar{u}$.

Volume Sources

Some possible non-DC source processes, such as polymorphic phase transformation, occur throughout a finite volume rather than on a surface. The equivalent force system often can be expressed in terms of the “stress-free strain” $\Delta_\sigma e_{ij}$, which is the strain that would occur in the source volume if the tractions on its boundary were held constant by externally applied artificial forces (It might more accurately be called the “fixed-stress strain.”). By reasoning that involves a sequence of imaginary cutting, straining, and welding operations (e.g., Aki and Richards 2002, Sect. 3.4), the moment tensor of such a volume source is found to be

$$M_{ij} = \iiint_V c_{ijkl} \Delta_\sigma e_{kl} dV. \quad (12)$$

For a stress-free volume change $\Delta_\sigma V$ in an isotropic medium, for example,

$$M_{ij} = K \Delta_\sigma V \delta_{ij}, \quad (13)$$

where $K = \lambda + (2/3)\mu$ is the bulk modulus.

The stress-free strain is *not*, in general, the strain that actually occurs in a seismic event (Richards and Kim 2005). Because the source is imbedded in the Earth, its deformation is resisted by the stiffness of the surrounding medium, making the true strain changes smaller than the

stress-free values. For example, in terms of the true volume change ΔV , the moment tensor of an isotropic source in an infinite isotropic elastic medium is

$$M_{ij} = (\lambda + 2\mu)\Delta_r V \delta_{ij}, \quad (14)$$

so

$$\Delta_r V = \frac{\lambda + (2/3)\mu}{\lambda + 2\mu} \Delta_\sigma V. \quad (15)$$

The distinction is quantitatively significant; for an infinite homogeneous Poisson solid, $\Delta_r V = (5/9)\Delta_\sigma V$. Furthermore, the stiffness seen by the source, and thus the true strain, depends on the elasticity structure outside the source volume.

Decomposing Moment Tensors

To make a general moment tensor easier to understand, it helps to decompose it into simpler force systems. First, we express the moment tensor in its principal axis coordinate system. Three values (the Euler angles, for example) are needed to specify the orientation of this system, and three other values specify the moments of three orthogonal dipoles oriented parallel to the coordinate axes. Writing these three principal moments as a column vector, we first decompose the moment tensor into an isotropic force system and a deviatoric remainder,

$$\begin{bmatrix} M_1 \\ M_2 \\ M_3 \end{bmatrix} = M^{(V)} \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix} + \begin{bmatrix} M'_1 \\ M'_2 \\ M'_3 \end{bmatrix}, \quad (16)$$

with $M^{(V)} \stackrel{\text{def}}{=} (M_1 + M_2 + M_3)/3$, and then decompose the deviatoric part into a DC (principal moments in the ratio 1 : -1 : 0) and a “compensated linear vector dipole” (CLVD), a source with principal moments in the ratio 1 : -1/2 : -1/2 (Knopoff and Randall 1970). Figure 1 illustrates the three elementary force systems used in this decomposition, showing their compressional-wave radiation patterns and the distributions of compressional-wave polarities on the focal sphere (an imaginary sphere surrounding the earthquake hypocenter, to which observations are often referred). Many other

decompositions of the deviatoric part are possible, including many decompositions into two DCs or into two CLVDs. The method of Knopoff and Randall (1970), which makes the largest axis of the CLVD coincide with the corresponding axis of the DC, avoids pathological behavior and is the method most widely used in seismological research:

$$\begin{bmatrix} M'_1 \\ M'_2 \\ M'_3 \end{bmatrix} = M^{(DC)} \begin{bmatrix} 0 \\ -1 \\ 1 \end{bmatrix} + M^{(CLVD)} \begin{bmatrix} -\frac{1}{2} \\ -\frac{1}{2} \\ 1 \end{bmatrix}, \quad (17)$$

with $M^{(DC)} = M'_1 - M'_2$, and $M^{(CLVD)} = -2M'_1$. The moment-tensor elements are arranged so that $|M'_1| \leq |M'_2| \leq |M'_3|$.

The quantity

$$\varepsilon \stackrel{\text{def}}{=} \frac{-M'_1}{|M'_3|} \equiv \frac{1}{2} \frac{M^{(CLVD)}}{|M^{(DC)} + M^{(CLVD)}|} \quad (18)$$

is sometimes used as a measure of the departure of the deviatoric part of a moment tensor from a pure DC. It ranges in value from zero for a pure DC to $\pm 1/2$ for a pure CLVD. Positive ε corresponds to extensional polarity for the major dipole of the CLVD component.

Displaying Focal Mechanisms

Focal-Sphere Polarity Plots

Since the 1960s, common practice has been to display DC mechanisms by showing the compressional-wave polarity fields on maps of a focal hemisphere, and this method is now also widely used for general symmetric moment tensors. Both azimuthal-equal-area (Lambert) and stereographic projections are used, with teleseismic data usually plotted on lower hemispheres and local data on upper hemispheres. Shaded fields usually represent positive polarities (outward first motions). Figures 2, 4, 6, 8, 9, 11, 12, and 13 below contain examples of focal-sphere polarity plots.

A disadvantage of focal-sphere polarity plots is that different mechanisms can lead to

Non-Double-Couple Earthquakes, Fig. 1 Three source types commonly used in decomposing moment tensors: (from left to right) isotropic, double couple (DC), and compensated linear-vector dipole (CLVD). *Top row:* equivalent force systems, in principal-axis

coordinates. For the DC, the force system in a fault-oriented coordinate system is shown underneath. *Second row:* compressional-wave radiation patterns. *Third row:* compressional-wave nodal surfaces. *Fourth row:* curves of intersection of nodal surfaces with the focal sphere

identical plots. Figure 2 shows, for example, that a rather wide range of mechanisms can have positive (or negative) compressional-wave polarities over the entire focal sphere.

Source-Type Plots
Focal-sphere polarity plots display information about source orientation as well as “source type” (the relative values of the principal

Non-Double-Couple Earthquakes, Fig. 2 *Top*: “Source-type plot” of Hudson et al. (1989), which displays earthquake mechanisms (symmetric moment tensors) without regard to their orientations. The quantity k (Eq. 19), which measures volume change, ranges from -1 at the *bottom* of the plot to $+1$ at the *top*, and is constant along the sub-horizontal grid lines. The quantity -2ε (Eq. 18), which describes the deviatoric part of the moment tensor, ranges from -1 on the *left-hand side* of the plot to $+1$ on the *right-hand side*, and is constant along the grid lines that run from *top* to *bottom*. DC: double-couple mechanisms; +Crack: Opening tensile faults;

+Dipole: Force dipoles with forces directed outward; +CLVD: “Compensated linear-vector dipoles,” with dominant dipoles directed outward. –Crack, –Dipole, and –CLVD: The same mechanisms with opposite polarities. *Shaded area*: Region in which all compressional waves have outward polarities. A similar region of inward polarities occurs at the *bottom* of the plot. *A–R*: Some representative mechanisms. *Bottom*: Conventional equal-area focal-hemisphere plots of compressional-wave polarities for 15 representative mechanisms shown on the source-type plot

moments). In fact, conventional DC polarity plots contain information about *only* source orientation. When considering non-DC mechanisms, however, it is useful to display the source type without regard to orientation. The normalized principal moments contain two independent degrees of freedom, and there are many possible ways to display such information in two dimensions. Figure 2 shows the “source-type plot” (Hudson et al. 1989), which gives $T^{\text{def}} = -2\varepsilon$ (Eq. 18) vs.

$$k \stackrel{\text{def}}{=} \frac{M^{(V)}}{|M^{(V)}| + |M'_3|}, \quad (19)$$

a measure of the volume change.

Determining Earthquake Mechanisms

Many types of seismic and geodetic data can be used to determine earthquake focal mechanisms. These range from simple polarities (signs) of observable quantities, through measurements of their amplitudes, to complete time histories of their evolution.

Wave Polarities

First-Motion Methods

P-phase polarities are the most commonly used data in focal-mechanism studies, because they can be determined easily, even using recordings of low dynamic range and accuracy from single-component seismometers. Such polarities alone are of very limited use, however, for studying (or even for identifying) non-DC earthquakes. Even with observations well distributed on the focal sphere, it usually is difficult to rule out DC mechanisms in practice. This difficulty is especially severe if the earthquake lacks a large isotropic component.

In analyzing *P*-wave polarities, seismologists usually constrain earthquake mechanism to be DCs. Finding a DC mechanism amounts to finding two orthogonal nodal planes (great circles on

the focal sphere) that separate the compressional and dilatational polarities into four equal quadrants. Three independent quantities (fault-plane strike and dip angles and the rake angle of the slip vector, say) are needed to specify the orientations of the nodal planes. Nodal planes can be sought either manually, by plotting data on maps of the focal sphere and using graphical methods to find suitable nodal planes, or by using computerized methods, most of which systematically search through the space of possible solutions.

Moment-Tensor Methods

For general moment-tensor mechanisms, hand-fitting mechanisms to observed polarities is impractical. The number of unknown parameters increases from three to five (the six moment tensor components, normalized in some arbitrary way), and furthermore the theoretical nodal surfaces become general ellipses, rather than great circles, on the focal sphere. Searching methods still work, but the addition of two more unknown parameters makes them costly in terms of computer time. Linear programming (sections “[Wave Amplitudes](#)” and “[Amplitude Ratios](#),” below), an analytical method that treats linear inequalities, is well suited to determining moment tensors from observed wave polarities (Julian 1986).

Near-Field Polarities

Near-field observations (made within a few wavelengths of the source) provide a simple and elegant method of detecting an isotropic source component using a single radial-component seismogram (McGarr 1992). The method is not guaranteed to detect isotropic components whenever they exist, but it involves few assumptions, so detected isotropic components are comparatively reliable.

Assume that all the moment-tensor components are proportional to the unit step function, $U(t)$ (any monotonic function of time will work). Place the origin of the coordinate system at the source, with the x_1 axis directed toward the

observer. Then from Eq. 4.29 of Aki and Richards (2002), in an infinite homogeneous medium the radial displacement (the x_1 component observed on the x_1 axis) is

$$u_1(t) = \frac{3}{4\pi\rho r^4} (3M_{11} - Tr\mathbf{M})w(t) \quad (20a)$$

$$+ \frac{1}{4\pi\rho V_P^2 r^2} (4M_{11} - Tr\mathbf{M})U(t - r/V_P) \quad (20b)$$

$$- \frac{1}{4\pi\rho V_S^2 r^2} (3M_{11} - Tr\mathbf{M})U(t - r/V_S) \quad (20c)$$

$$+ \frac{1}{4\pi\rho V_P^3 r} M_{11}\delta(t - r/V_P), \quad (20d)$$

where

$$w(t) \stackrel{\text{def}}{=} \int_{r/V_P}^{r/V_S} \tau U(t - \tau) d\tau \quad (21)$$

vanishes for $t \leq r/V_P$, increases monotonically for $r/V_P \leq t \leq r/V_S$, and is constant for $r/V_S \leq t$. Here $r \equiv x_1$ is the source-observer distance and V_P and V_S are the compressional- and shear-wave speeds. The near-field term Eq. 20a produces a monotonic trend on the seismogram between the compressional and shear waves. For a purely deviatoric source ($Tr \mathbf{M} = 0$), the polarity of this near-field term must be the same as that of the compressional wave Eqs. 20b and 20d. Opposite polarities on any radial seismogram imply that the source mechanism has an isotropic component. Similarly, the near-field shear wave Eq. 20c must have the opposite polarity to the compressional wave, and any observations to the contrary indicate an isotropic source component.

Polarities of Other Seismic Waves

The polarities of shear waves can furnish valuable information to complement compressional-wave first motions, but because shear seismic phases arrive later in the seismogram, where scattered energy (“signal-generated noise”) is also arriving, their polarities often are difficult

to measure reliably. An additional severe difficulty arises for vertically polarized shear (SV) waves incident at the surface beyond the critical angle $\sin^{-1}(V_S/V_P)$ (at epicentral distances between about 0.7 times the focal depth and several thousand kilometers). Outside the “shear-wave windows” at small and large distances, incident shear waves excite evanescent compressional waves that complicate signals and render them practically useless for analysis (Booth and Crampin 1985). Still another problem arises because wave scattering by heterogeneities near the surface excites compressional waves that arrive slightly before the direct shear wave, making the true S onset difficult to identify. These latter two difficulties are caused by conditions at or near the free surface and can be partially alleviated by installing seismometers in deep boreholes.

None of these problems affect horizontally polarized shear waves in spherically symmetric media, and in practice useful *SH* polarities can usually be determined reliably on transverse-component seismograms obtained by numerical rotation.

Wave Amplitudes

The amplitude of a radiated seismic wave contains far more information about the earthquake mechanism than does its polarity alone, so amplitude data can be valuable in studies of non-DC earthquakes. Moreover, because seismic-wave amplitudes are linear functions of the moment-tensor components, determining moment tensors from observed amplitudes is a linear inverse problem, which can be solved by standard methods such as least squares. Conventional least-squares methods, however, cannot invert polarity observations such as first motions, which typically are the most abundant data available. Linear programming methods, which can treat linear inequalities, are well suited to inverting observations that include both amplitudes and polarities (Julian 1986). In this approach, bounds are placed on observed amplitudes, so that they can be expressed as linear inequality constraints. Polarities are already in

the form of linear inequality constraints if the moment-tensor representation is used.

Linear programming methods seek solutions by attempting to minimize the L1 norm (the sum of the absolute values) of the residuals between the constraints and the theoretical predictions.

Amplitude Ratios

Seismic-wave amplitudes are subject to distortion during propagation, particularly because of focusing and de-focusing by structural heterogeneities. A simple way to reduce the effect of this distortion when deriving earthquake mechanisms is to use as data the ratios of amplitudes of waves that have followed similar paths, such as $P:SV$, $P:SH$, or $SH:SV$. If the ratios of the wave speeds is constant in the Earth, then the amplitudes of the waves are affected similarly and the ratio is relatively unaffected.

Using amplitude ratios makes inverting for source mechanisms more difficult, however, because a ratio is a nonlinear function of its denominator. Systematic searching methods still work, but because the dimensionality of the model space is increased by two over that for a DC mechanism, the computational labor is greatly increased (typically by a factor of more than 100).

The efficient linear programming method described above is easily extended to treat amplitude-ratio data in addition to polarities and amplitudes (Julian and Foulger 1996). An observed ratio is expressed as a pair of bounding values, each of which gives a linear inequality that is mathematically equivalent to a polarity observation with a suitably modified Green's function.

Waveforms

A digitized waveform is just a series of amplitude measurements, so waveform inversion may be regarded as an extension of amplitude inversion.

Mathematical Formulation

A theoretical seismogram can be written as a sum of terms, each of which is the temporal convolution of a Green's function and the time function of one source component (Eq. 6).

The source components can include components of the equivalent force and moment-tensor components of any order. If there are n such source components (six, in the usual case of a symmetric second-rank moment tensor), which we arrange in a column vector $\phi(t)$, then a set of m seismograms corresponds to the system of simultaneous equations

$$\begin{bmatrix} u_1(t) \\ u_2(t) \\ \vdots \\ u_m(t) \end{bmatrix} = \begin{bmatrix} A_{11}(t) & \cdots & A_{1n}(t) \\ A_{12}(t) & \cdots & A_{2n}(t) \\ \vdots & \ddots & \vdots \\ A_{m1}(t) & \cdots & A_{mn}(t) \end{bmatrix} * \begin{bmatrix} \phi_1(t) \\ \phi_2(t) \\ \vdots \\ \phi_n(t) \end{bmatrix}, \quad (22)$$

where each matrix element A_{ij} is a Green's function giving the i th seismogram generated by a source whose j th component is the impulse $\delta(t)$, and whose other components are zero. The symbol $*$ indicates temporal convolution. The Green's functions can be thought of as a multichannel filter, which takes the n source time functions $\phi_j(t)$ as inputs and generates as output the m synthetic seismograms $u_i(t)$.

Estimating the source time functions from a set of observed seismograms and assumed Green's functions is thus a multichannel inverse filtering, or deconvolution, problem. It can be solved, for example, by transforming to the frequency domain (so that the convolutions become multiplications) and then applying standard least-squares methods to solve for each spectral component. Alternatively, the output seismograms in Eq. 22 can be concatenated into a single time series, and the Green functions in each column of the matrix $\mathbf{A}$ similarly concatenated. Then, when each time series is expressed explicitly in terms of its samples, the least-squares normal equations turn out to have a "block-Toeplitz" structure, so that they can be solved efficiently by Levinson Recursion (Sipkin 1982).

Limitations

Imperfect Earth Models

If the Earth model used to analyze the radiation from an earthquake differs from the true structure

of the Earth, systematic errors will be introduced into the Green functions and thus into inferred source mechanisms. Near-source anisotropy (section “[Shear Faulting in an Anisotropic Medium](#)”) is one cause of such errors.

Deficient Combinations of Modes

Even if the Green’s functions are correct, it may be impossible to determine the source mechanism completely in some circumstances. For particular types of seismic waves, there may be certain source characteristics that cannot be determined. For example, shear waves alone cannot detect isotropic source components, because purely isotropic sources do not excite shear waves. Similarly, sources with vertical symmetry axes (those whose only nonzero components are $M_{11} = M_{22}$ and M_{33} , with the x_3 axis vertical) excite no horizontally polarized shear (*SH*) or Love waves, and cannot be detected using such waves alone. For any Rayleigh mode, the component M_{33} occurs only in the combination $M_{11} + M_{22} + f(\omega)M_{33}$, where the frequency function $f(\omega)$ depends on the mode and the Earth model. The M_{33} component can be traded off against $M_{11} + M_{22}$ without changing this combination, so isotropic sources are unresolvable by Rayleigh waves of a single frequency and mode (Mendiguren 1977), and even with multimode observations, determining M_{33} requires a priori assumptions about its spectrum. In most studies, enough different modes and/or frequencies are used so that none of these degenerate situations arises. Furthermore, all general inversion methods in widespread use provide objective information about uncertainty and nonuniqueness in derived values, so degeneracies can be detected if they happen to occur.

Shallow Earthquakes

If an earthquake is effectively at the free surface (shallow compared to the seismic wavelengths used), then it is impossible to determine its full moment tensor. Only three moment-tensor components can be determined, and these are not enough even under the a priori assumption of a DC mechanism (which requires four parameters). This degeneracy follows from the

proportionality between the coefficient C_{ij} giving the amplitude of a seismic mode excited by the moment-tensor component M_{ij} and the displacement derivative $u_{i,j}$ for the mode. (This proportionality follows from the principle of reciprocity.) Vanishing of the traction on the free surface,

$$\begin{aligned}\sigma_{13} &= \mu(u_{1,3} + u_{3,1}) = 0 \\ \sigma_{23} &= \mu(u_{2,3} + u_{3,2}) = 0 \\ \sigma_{33} &= \lambda(u_{1,1} + u_{2,2}) + (\lambda + 2\mu)u_{3,3} = 0,\end{aligned}\tag{23}$$

implies that three linear combinations of the excitation coefficients vanish:

$$\begin{aligned}C_{13} &= 0 \\ C_{23} &= 0 \\ \lambda C_{11} + \lambda C_{22} + (\lambda + 2\mu)C_{33} &= 0.\end{aligned}\tag{24}$$

(Here we restrict ourselves to symmetric moment tensors.) Therefore a moment tensor whose only nonzero components are M_{13} and M_{23} radiates no seismic waves (to this order of approximation), and moreover a diagonal moment tensor with elements in the ratio $\lambda : \lambda : (\lambda + 2\mu)$ likewise radiates no seismic waves. The first case corresponds to a vertical dip-slip shear fault or a horizontal shear fault, and the second corresponds to a horizontal tensile fault. This second undeterminable source type has an isotropic component, so isotropic components cannot be determined for shallow sources.

This degeneracy is most often important in studies using surface waves or normal modes, because these are usually observed at frequencies below 0.05 Hz, for which the wavelengths are greater than the focal depths of many earthquakes.

Non-DC Earthquake Processes

Processes Involving Net Forces

Most experimental investigations of earthquake source mechanisms have excluded net forces and torques from consideration a priori. As discussed

above in section “[Net Forces and Torques](#),” the laws of physics do not require such restrictions. Net forces are possible for an internal source because momentum can be transferred between the source region and the rest of the Earth. Momentum conservation does, however, require that the impulse (time integral) of the net force component must vanish if the source is at rest before and after the event.

Landslides

Among sources that involve net forces, landslides have received the most attention. Modeling a landslide as a block of mass M sliding down a ramp gives an equivalent force of $-M\mathbf{a}$, where $\mathbf{a}$ is the acceleration of the block.

The gravitational forces on a landslide also produce a torque of magnitude $Mg\Delta x$, where g is the acceleration of gravity and Δx is the horizontal distance the slide travels.

Volcanic Eruptions

The eruption of material by a volcano applies a net force to the Earth, much as an upward-directed rocket exhaust would. Of course, the total impulse imparted to the Earth-atmosphere system is zero, as with any internal source, but the spatially and temporally concentrated force at the volcanic vent can generate observable seismic waves, whereas the balancing forces transmitted from the ejected material through the atmosphere back to the Earth’s surface excite waves that probably are unobservable in practice. Therefore a volcanic eruption may be modeled as a point force $S\Delta P$, where S is the area of the vent and ΔP is the pressure difference between the source reservoir within the volcano and the atmosphere (Kanamori et al. 1984).

Other processes accompanying volcanic eruptions might act as seismic-wave sources. A change in pressure in a deep spherically symmetric reservoir acts as an isotropic source with a moment tensor given by Eq. 14 (section “[Volume Sources](#)”). For a tabular or crack-shaped reservoir, the force system is the same as that for a tensile fault, discussed in sections “[Tensile Faults](#)” and “[Tensile Faulting](#).”

Unsteady Fluid Flow

If the speed, and thus the momentum, of fluid flowing in a conduit varies with time, a time-varying net force,

$$\mathbf{F} = - \iiint_V \rho \mathbf{a} dV, \quad (25)$$

is exerted on the surrounding rocks, where ρ is the density of the fluid and $\mathbf{a}$ is its acceleration. This process may cause “long-period” volcanic earthquakes and the closely related phenomenon of volcanic tremor. Time variations in the flow speed might be caused by the breaking of barriers to flow, or be self-excited by nonlinear interaction between the flowing fluid and deformable channel walls (Julian 1994).

Complex Shear Faulting

Multiple Shear Events

If earthquakes occur close together in space and time, observed seismic waves may not be able to resolve them, and they may be misinterpreted as a single event. The apparent moment tensor of the composite event is then the sum of the true moment tensors of the earthquakes, and because the sum of two DCs is not, in general, a DC, shear faulting can produce non-DC mechanisms in this way. Combining DCs cannot ever produce mechanisms with isotropic (volume change) components, because the trace of the moment tensor is a linear function of its components, so multiple shear-faulting mechanisms lie on the horizontal axis of the source-type plot.

By analyzing complete seismic waveforms, it is often possible to resolve a multiple event into subevents with different mechanisms. Doing this requires use of algorithms that allow the moment tensor to vary with time in a general way. Algorithms that assume that all the moment-tensor components have identical time functions can produce spurious non-DC mechanisms, even if the subevents have identical DC mechanisms.

Volcanic Ring Faults

Dikes intruded along conical surfaces with both outward and inward dips are often found in

Non-Double-Couple Earthquakes, Fig. 3 Geometry of volcanic ring faulting used in computing mechanisms shown in Fig. 4. Dip-slip motion on fault of dip δ is uniformly distributed over azimuth range θ

exhumed extinct volcanoes, and are expected consequences of the stresses caused by inflation and deflation of magma chambers (Anderson 1936). These dikes are of two types: “cone sheets,” which dip inward at about $30\text{--}70^\circ$, form as tensile faults during inflation, and nearly vertical or steeply outward-dipping “ring dikes” form through shear failure accommodating subsidence following deflation or eruption of magma. For both types, the axes of the cones are approximately vertical. If dip-slip shear faulting occurs on a conical fault, and the rupture in an earthquake spans a significant azimuth range (Fig. 3), the resulting mechanism, considered as a point source, can have a non-DC component (Ekström 1994). (Strike-slip motion on such a surface always gives pure DC mechanisms.) Figure 4 shows a suite of theoretical source mechanisms corresponding to dip-slip ruptures spanning various azimuth ranges on conical faults of different dips. For steeply dipping faults the non-DC components are small (for vertical faults they vanish), so cone sheets are more efficient than ring dikes as a non-DC process.

Tensile Faulting

Opening Tensile Faults in the Earth

An obvious candidate mechanism for geothermal and volcanic earthquakes is tensile faulting, in which the displacement discontinuity is normal,

rather than parallel, to a fault surface. The equivalent force system of a tensile fault consists of three orthogonal linear dipoles with moments in the ratio $(\lambda + 2\mu):\lambda:\lambda$. It is equivalent to an isotropic source of moment $(\lambda + 2\mu/3)A\bar{u}$ plus a CLVD of moment $(4\mu/3)A\bar{u}$ (section “[Tensile Faults](#)”). The far-field compressional waves have all first motions outward, with amplitudes largest (by a factor of $1 + 2\mu/\lambda$) in the direction normal to the fault. Figure 2 shows the position of tensile faults on a source-type plot.

Compressive stress tends to prevent voids from forming at depth in the Earth, but high fluid pressure can overcome this effect and allow tensile failure to occur. The situation is conveniently analyzed using Mohr’s circle diagrams (Fig. 5). The effect of interstitial fluid at pressure p in a polycrystalline medium such as a rock is to lower the effective principal stresses by the amount p . Thus fluid pressure, if high enough, can cancel out much of the compressive stress caused by the overburden. Fluid pressures comparable to the lithostatic load are found surprisingly often in deep boreholes.

A second prerequisite for tensile failure is that the shear stresses be small, or equivalently that the principal stresses be nearly equal. The diameter of the Mohr’s circle in Fig. 5 is equal to the maximum shear stress (difference between the extreme principal stresses). If this diameter is too large, the circle can touch the failure envelope only along its straight portion, which corresponds to shear failure. Only if the shear stress, and thus the diameter, is small will the circle first touch the failure envelope in the tensile field to the left of the τ axis.

Combined Tensile and Shear Faulting

Although tensile faults could cause earthquakes that involve volume increases, they cannot explain non-DC earthquakes whose isotropic components indicate volume decreases. Tensile faults can open suddenly for a variety of reasons, but they would be expected to close gradually, and not to radiate elastic waves. If a tensile fault and a shear fault intersect, however, then stick-slip instability could cause sudden episodes of either opening or closing, with volume increases or decreases. The stresses around the

Non-Double-Couple Earthquakes,

Fig. 4 Non-DC mechanisms for volcanic ring faulting (Fig. 3). Theoretical compressional-wave nodal surfaces for an arcuate dip-slip fault whose strike spans a range θ and averages north-south. Each focal sphere corresponds to two situations: a fault dipping to the west by the smaller angle δ given or to the east by the larger angle. All mechanisms are purely deviatoric. Numbers below each mechanism give values of ε (Eq. 18), which describe the deviatoric parts of the moment tensors. Upper focal hemispheres are shown in equal-area projection. Lower hemisphere plots are *left-right* mirror images. For normal faulting, central fields have dilatational polarity

tips of both shear and tensile faults favor this type of fault pairing, and faulting of this kind occurs in rocks in the laboratory (Brace et al. 1966). A similar situation can occur in the case of shear faulting near mines, with the tunnel playing the role of the tensile fault.

Figure 6 shows the theoretical source mechanisms for combined tensile and shear faults of different geometries and relative seismic moments. When the tensile fault opens or closes in the direction normal to its face, the

mechanisms have large isotropic components, with most of the focal sphere having the same polarity as the tensile fault and two unconnected fields having the opposite polarity. The symmetry of the moment tensors makes it impossible to determine the angle between the two faults. An angle of $45^\circ - \alpha$ is equivalent to an angle of $45^\circ + \alpha$. When the tensile fault opens or closes obliquely, in the direction parallel to the shear fault, then the mechanisms are closer to DCs, and less sensitive to the relative seismic moments.

Non-Double-Couple Earthquakes, Fig. 5 Conditions for shear and tensile failure. Mohr's circle diagram shows the relationship between shear traction τ and normal traction σ across a plane in a stressed medium. Locus of (σ, τ) points for different orientations of the plane is a circle of diameter $\sigma_1 - \sigma_3$, centered at $((\sigma_1 + \sigma_3)/2)$, where σ_1 and σ_3 are the extreme principal stresses. Failure occurs when circle touches the "failure envelope," and the point of tangency determines the orientation of the resulting fault (see *inset*). (Theoretical failure envelope shown corresponds to Griffith theory of failure, as modified by F. A. McClintock and J. B. Walsh (Price 1966).) Straight portion of failure envelope in compressional field ($\sigma > 0$) represents the Navier-Coulomb criterion for shear failure. (Top) At high confining stress with no fluid pressure, only shear failure occurs. (Bottom) High fluid pressure lowers the effective confining stress, and tensile failure occurs for low stress differences

If the dominant principal axis of the tensile fault lies in the same plane as the P and T axes of the shear fault (i.e., if the null axis of the shear fault lies in the tensile-fault plane), then the composite mechanism lies on the line between the DC and Crack positions on a focal-sphere plot. For more general (and less physically plausible) geometrical arrangements,

the composite mechanism lies within a region consisting of two triangles (Fig. 7).

Shear Faulting in an Anisotropic Medium

The equivalent force system of an earthquake depends on the constitutive law used to compute the model stress s_{ij} in Eq. 2. This means that a fault in an anisotropic elastic medium has a different equivalent force system than it would if the medium were isotropic, and in particular that a shear fault in an anisotropic medium generally has a non-DC moment tensor, which can be determined, for example, from Eq. 11 (Vavryčuk 2005). Most rocks are anisotropic, because of layering on a scale smaller than seismic wavelengths, preferential orientation of crystals, and the presence of cracks and inclusions, so most earthquakes are affected by anisotropy.

Elastic wave propagation in an anisotropic medium is more complicated in several ways than in an isotropic medium. The particle motion in body waves is no longer either longitudinal or transverse to the direction of propagation, but is generally oblique, so body-wave modes are referred to as "quasi-compressional" and "quasi-shear." The "direction of propagation," in fact is no longer a single direction, but rather two directions for each mode: the normal to the wavefront (the "phase velocity" direction) and the direction of energy transport (the "group velocity" direction, from the source to the observer).

Green's functions for the anisotropic medium must be used to compute the radiated seismic waves for the force system given by Eq. 11 (Gajewski 1993) and to solve the inverse problem of determining the force system from observed seismograms. If enough information is available about source-region anisotropy to determine such Green's functions, then it will be possible to recognize when non-DC force systems are consistent with shear faulting. In practice, however, information about anisotropy in earthquake focal regions is seldom available, so Green's functions appropriate for isotropic constitutive laws are used instead. In this case, the non-DC force system of most interest is not the one given by Eq. 11, but rather the one that would be derived

Non-Double-Couple Earthquakes,

Fig. 6 Non-DC mechanisms for combined tensile and shear faulting with different geometries. Both faults are vertical, with the shear fault striking north-south and the tensile fault striking west of north at the angle α , indicated by bold ticks. *Left column:* tensile fault opening normal to its face. *Right column:* tensile fault opening obliquely, parallel to the shear fault. Compressional-wave nodal surfaces are shown for different relative moments of the tensile (M^T) and shear (M^S) components. *Solid curves:* $M^T = 0.5M^S$. *Dashed curves:* $M^T = 0.2M^S$. *Dotted curves:* $M^T = 0.1M^S$. Numbers to the right of each plot give values of k and ϵ (Eqs. 18 and 19), for each mechanism. Focal hemispheres (either upper or lower, because of symmetry) are shown in equal-area projection

from seismic waves using an isotropic constitutive law when the focal region is actually anisotropic.

Shear Faulting in a Heterogeneous Medium

If an earthquake occurs in a place where the elastic moduli vary spatially, its apparent mechanism will be distorted, and a DC earthquake may appear to have non-DC components. This occurs when the spatial derivatives of Green's functions (strains) appearing in the second term on the right side of

the moment expansion Eq. 6 vary significantly over the source region, so that the values at $\xi = 0$ are inappropriate for a portion of the moment release. In effect, neglected higher moments are contaminating estimates of the lower moments.

This effect is *not* a consequence of using an incorrect Earth model to compute the Green function. In this discussion, we assume that the Earth model and Green's function are exact. The distortion of the focal mechanism is caused by the finiteness of the source region. Errors in the

Non-Double-Couple Earthquakes, Fig. 7 Source types for combined tensile and shear faulting. Numbers give angles between the tensile-fault planes and the intermediate principal (null) axes of the shear faults. Small angles are physically most plausible (For the mechanisms shown in Fig. 6 this angle is zero.). For all possible relative

orientations and moments, the source type lies between the corresponding curve and the *straight line* from +Crack to -Crack. The upper half of the plot corresponds to opening faults and the lower half to closing faults. For an explanation of the plotting method, see Fig. 2

Green function due to our incomplete knowledge of Earth structure and to the mathematical complexity of elastodynamics can cause severe errors in derived earthquake mechanisms, but that is a different phenomenon.

Consider an earthquake near an interface across which the elastic moduli change discontinuously (Woodhouse 1981), so that the truncated Taylor series Eq. 5 is a particularly poor approximation. Then the inferred mechanism of an earthquake that is assumed to occur on one side of the interface will be distorted if the earthquake actually is on the other side. If the source region includes both sides of the interface, it is unavoidable that a portion of the moment release will be distorted in this manner.

If we arrange the independent components of the moment tensor in a column vector,

$$\mathbf{m}^{\text{def}} [M_{11} \ M_{12} \ M_{22} \ M_{13} \ M_{23} \ M_{33}]^T, \quad (26)$$

then the seismic waves excited can be written $\mathbf{g}^T \mathbf{m}$, where $\mathbf{g}$ is a column vector whose

components are spatial derivatives of Green's functions appearing in the second term on the right side of Eq. 6. Because displacement and stress are continuous at the interface, the elements of $\mathbf{g}$ on one side of the interface are related to those on the other side by a relation that can be written

$$\mathbf{A}^+ \mathbf{g}^+ = \mathbf{A}^- \mathbf{g}^-, \quad (27)$$

where $\mathbf{A}$ is a matrix that depends on the orientation of the interface and the elastic moduli adjacent to it, and the superscripts $+$ and $-$ indicate values on the two sides of the interface. It follows that

$$\mathbf{g}^{+T} \mathbf{m} = \mathbf{g}^{-T} [\mathbf{A}^{+-1} \mathbf{A}^-]^T \mathbf{m}, \quad (28)$$

or in other words that an earthquake with moment tensor $\mathbf{m}$ occurring on the $+$ side of the interface excites the same waves as an earthquake with moment tensor $[\mathbf{A}^{+-1} \mathbf{A}^-]^T \mathbf{m}$ occurring on the opposite ($-$) side. In a coordinate

system with the x_3 axis normal to the interface, the matrix connecting the true and apparent moment tensors is

$$[\mathbf{A}^{+-1}\mathbf{A}^-]^T = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & R_1 \\ 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & R_2 & 0 & 0 \\ 0 & 0 & 0 & 0 & R_2 & 0 \\ 0 & 0 & 0 & 0 & 0 & R_3 \end{bmatrix}, \quad (29)$$

where

$$R_1 \stackrel{\text{def}}{=} \frac{\lambda^- - \lambda^+}{\lambda^+ + 2\mu^+}, \quad (30)$$

$$R_2 \stackrel{\text{def}}{=} \frac{\mu^-}{\mu^+}, \quad (31)$$

and

$$R_3 \stackrel{\text{def}}{=} \frac{\lambda^- + 2\mu^-}{\lambda^+ + 2\mu^+}. \quad (32)$$

Figure 8 shows the distortion of the apparent mechanisms of DCs of various orientations occurring adjacent to a horizontal interface across which the elastic-wave speeds change by 20 %. If the fault plane is parallel to the interface (or if the interface *is* the fault plane), then shear faulting does not lead to apparent non-DC mechanisms, although the scalar seismic moment is distorted. This case is not illustrated in the figure, but is clear from the structure of the matrix in Eq. 29. Only M_{13} and M_{23} are nonzero and matrix multiplication merely multiplies these elements by R_2 , producing a DC of the same orientation, but with its moment multiplied by the contrast in rigidity modulus. If the fault is perpendicular to the interface, then the apparent mechanism is still a DC for all slip directions, but its orientation and seismic moment are distorted, as the first column of the figure illustrates. For general fault orientations, the apparent mechanism has artificial isotropic and CLVD components.

Rapid Polymorphic Phase Changes

Except in the shallow crust, compressional stresses in the Earth greatly exceed shear stresses. Therefore, earthquake processes that involve even relatively small volume changes could release large amounts of energy. For this reason, it has long been speculated that polymorphic phase transformations in minerals might cause deep earthquakes. Such speculation has been stimulated also by consideration of the simple theory of frictional sliding, which seems to require impossibly large shear tractions when the confining pressure is high, and by the theory of plate tectonics, which involves large-scale vertical motions in the upper mantle. Many common minerals undergo polymorphic changes in crystal structure in response to changes in pressure and temperature, and some of the major structural features in the Earth, most notably the “transition region” at depths between about 400 and 800 km in the upper mantle, are attributed to such phase changes (in this case, involving the mineral olivine, $(\text{Fe, Mg})_2\text{SiO}_4$, transforming to the spinel and then perovskite crystal structures).

As slabs of lithosphere subduct into the mantle, olivine and other minerals are carried out of their stability fields and into the stability fields of denser phases, into which they transform. If these changes occur rapidly enough to radiate seismic waves, they constitute earthquakes, and their mechanisms will have isotropic components. They probably will also have deviatoric components, because the process of phase transformation will release shear strain, much as explosions are often observed to release tectonic shear strain. There seems to be no reason, however, why such a deviatoric component should be a DC rather than a CLVD, and in fact the CLVD force system was first invented as a possible mechanism for deep earthquakes caused by phase transformations (Knopoff and Randall 1970).

Observations

Non-DC earthquakes are observed in many environments, including volcanic and geothermal areas, mines, and deep subduction zones.

Non-Double-Couple Earthquakes, Fig. 8 Apparent non-DC mechanisms caused by shear faulting with unit moment near a horizontal interface, for various dip and rake angles. *Solid curves*: compressional-wave nodal planes corresponding to true (DC) mechanisms. *Dotted curves*: nodal surfaces for apparent mechanisms obtained if DC moment release on the low-speed side of interface is assumed to be on the high-speed side. *Dashed curves*: same, with sides interchanged. Both media are Poisson solids, and the ratio of elastic moduli across the interface

is 1.7:1, corresponding to a wave-speed contrast of about 20 % if density is proportional to wave speed. Numbers below each mechanism give the DC moment and the values of k and ϵ (Eqs. 18 and 19) corresponding to the *dotted curves*. Dips of 0 are not shown because the apparent mechanisms are DCs (although with moments distorted by the ratio of the rigidity moduli). Dips of 90° correspond to cases with rake of 0 (first column). Focal hemispheres (which may be considered either upper or lower) are shown in equal-area projection

They include both natural earthquakes and events induced by human activity. An in-depth review of many observed examples is given by Miller et al. (1998b).

Landslides and Volcanic Eruptions

Landslides and volcanic eruptions have equivalent force systems that include net forces (section “Landslides”). An example is the Mount

St. Helens, Washington, eruption of May 18, 1980, which began with a landslide with a mass of about 5×10^{13} kg that traveled about 10 km from the volcano. The seismic observations are well explained by two forces, a near-horizontal, southward directed force representing the landslide, and a vertical force representing the eruption (Kanamori et al. 1984).

The gravitational forces on a landslide also exert a torque, which can be substantial, on the source volume (section “[Landslides](#)”). The dimensions of the landslide that accompanied the May 18, 1980, eruption of Mt. St. Helens, for example, correspond to a net torque of about 5×10^{18} N m. By comparison, the two largest earthquakes accompanying the eruption had surface-wave magnitudes of about 5.3, which correspond to seismic moments of about 2.6×10^{17} N m. Apparently, no seismological analyses of landslides to date have included torques in the source mechanism.

Long-Period Volcanic Earthquakes

Long-period volcanic earthquakes have dominant seismic frequencies an order of magnitude lower than those of most earthquakes with comparable magnitudes. They are caused by unsteady flow of underground magmatic fluids and are expected to have mechanisms involving net forces (section “[Unsteady Fluid Flow](#)”). An example is a 33-km-deep, long-period earthquake that occurred a year before the 1986 eruption of Izu Ōshima volcano, Japan. The seismograms are characterized by nearly monochromatic shear-wave trains that have dominant frequencies of about 1 Hz and last for more than a minute. The shear-wave polarization directions are consistent with a net force mechanism.

Several types of non-DC earthquakes occur at the intensively monitored active Sakurajima volcano in southern Kyushu, Japan. It is a rich source of low-frequency earthquakes and explosion earthquakes, which accompany crater eruptions that radiate spectacular visible shock waves into the atmosphere. The moment tensors of the explosion earthquakes have been explained as either deflation of cracks or other cavities that might rapidly expel gas into the

atmosphere (Uhira and Takeo 1994), or as sources dominated by vertical dipoles involving, for example, the opening of horizontal cracks (Iguchi 1994). The discrepancies between the results of these two studies reflect the difficulty of distinguishing between vertical forces and vertical dipoles.

Short-Period Volcanic and Geothermal Earthquakes

Observations from dense local seismic networks show that earthquakes in volcanic areas commonly have non-DC mechanisms. In many cases, the data have been subjected to careful analysis, including waveform modeling (e.g., Dreger et al. 2000; Julian and Sipkin 1985), corrections for wave propagation through three-dimensional crustal structure determined from tomography (e.g., Miller et al. 1998a; Ross et al. 1996), and the use of multiple seismic phases. The clearest cases are from Iceland, California, and Japan.

Three volcano-geothermal areas on the spreading plate boundary in Iceland are rich sources of short-period, non-DC earthquakes. These are the Reykjanes, Hengill-Greisdalur, and Krafla volcanic-geothermal systems. At all three areas, small earthquakes occur that have unequal dilatational and compressional areas on the focal sphere, suggestive of isotropic components in their mechanisms. The non-DC earthquakes are intermingled spatially with DC events, indicating that the non-DC mechanisms are not artifacts of instrumental errors or propagation through heterogeneous structures.

The Hengill-Greisdalur triple junction is the best studied of these areas. It was there that experiments were first performed in sufficient detail to demonstrate beyond reasonable doubt that non-DC earthquakes with net volume changes occur in nature (Foulger 1988; Miller 1998a) (Fig. 9). The area is currently the richest source of extreme non-DC earthquakes known. Approximately 70 % of the earthquakes involve volume increases, i.e., their radiation patterns are dominated by compressions, and they are thought to be caused by thermal contraction in the heat source of the geothermal area (Fig. 10).

Non-Double-Couple Earthquakes, Fig. 9 Map of the Hengill-Greisdalur volcanic complex, Iceland, showing focal mechanisms of nine representative earthquakes. Events 5, 6, 8, and 9 are indistinguishable from DCs. Compressional-wave polarities (*solid circles* indicate compressions; *open circles* indicate dilatations) and *P*-wave nodes are shown in upper focal hemisphere equal area projection. *Squares* denote downgoing rays plotted on the upper hemisphere. *T*, *I*, and *P* are positions of principal axes. *Lines* indicate epicentral locations. Where *lines* are absent, mechanisms are centered on epicenters. *Triangles* indicate seismometer locations; *dashed lines* show outlines of the main volcanic centers

Non-Double-Couple Earthquakes, Fig. 10 Schematic illustration of seismogenic tensile cracking by thermal stresses caused by convective cooling of rocks at the heat source of a geothermal system (From Foulger 1988)

Non-Double-Couple Earthquakes,

Fig. 11 Non-shear fault plane delineated by earthquake hypocenters. Views from three orthogonal directions showing the locations of 314 earthquakes (*black dots*) that lie between 2 and 5 km depth. *Upper left*: map view; *upper right*: SSW-NNE vertical cross-section; *lower left*: WNW-ESE vertical cross-section. *Star*: earthquake whose focal mechanism is shown at *lower right* as an upper-hemisphere plot of compressional-wave polarities. The mechanism for this earthquake is compatible with compensated tensile failure

The source mechanisms require more than simple tensile cracking, because the radiation patterns include both compressions and dilatations. Fluid flow and/or shear faulting probably also contribute components.

Non-DC geothermal earthquakes with volumetric mechanisms occur also at several volcanic-geothermal areas in California, including the Geysers steam field (Ross et al. 1996), the Coso Hot Springs (Julian et al. 2010), and Long Valley caldera (Foulger et al. 2004). Industrial steam extraction and water reinjection at the Geysers induces thousands of small earthquakes per month in the reservoir. The mechanisms are typically closer to DCs than those of Icelandic geothermal earthquakes, and the volumetric non-DC components range from explosive to implosive, with approximately equal numbers of each type.

Non-DC earthquake focal mechanisms were observed at the Coso Hot Springs geothermal field, California, in March 2005. There, a fluid injection activated a fault plane on which earthquakes with non-DC mechanisms of uniform type occurred. These involved volume increases. The orientation of the mechanisms relative to the

fault plane implied a process dominated by tensile failure with subsidiary shear faulting.

Abundant non-DC earthquakes were observed in a detailed experiment at Long Valley caldera in 1997. More than 80 % of the mechanisms had explosive volumetric components and most had compensated linear-vector dipole components with outward-directed major dipoles. The simplest interpretation of these mechanisms is combined shear and extensional faulting accompanied by a volume-compensating process such as the rapid flow of water, steam, or CO₂ into opening tensile cracks. A particularly well-recorded swarm was consistent with extensional faulting on an ESE-striking subvertical plane, an orientation consistent with the activated zone defined by the earthquake hypocenters. The orientations of non-DC earthquakes beneath Mammoth Mountain, a volcanic cone on the southwestern caldera rim, varied systematically with location, reflecting a variable local stress field. Events in a spasmodic burst indicated nearly pure compensated tensile failure and high fluid mobility (Foulger et al. 2004) (Fig. 11). Earthquakes with M_W 4.6–4.9 observed at

Non-Double-Couple Earthquakes,

Fig. 12 Long Valley caldera, California, and vicinity, showing the best located earthquakes in 1980 and mechanisms for the largest earthquakes of 1978 and 1980 as lower-hemisphere, equal-area projections, with fields of compressional-wave polarity in black

regional distances on broadband sensors also had non-DC moment tensors with significant volumetric components and were probably caused by hydrothermal or magmatic processes (Dreger et al. 2000).

Earthquakes with non-DC radiation patterns, some of them moderately large, accompany magmatic and volcanic activity. Many non-DC earthquakes with P -wave polarities that are either all dilatational or all compressional accompanied the 1983 eruption of Miyakejima volcano, Japan. The earthquakes radiated significant shear waves, indicating that their mechanisms were not purely isotropic. The P -wave polarities and P - and SV -wave amplitudes are compatible with combined tensile and shear faulting (section “Combined Tensile and Shear Faulting”), an interpretation supported by the numerous open cracks that formed prior to the eruption. A similar but substantially larger earthquake, of magnitude 3.2, occurred 10 km beneath the Unzen volcanic region, western Kyushu, in 1987 (Shimizu et al. 1987).

Long Valley caldera, in eastern California, has experienced some of the largest clearly non-DC

volcanic earthquakes. Four events with M_L greater than six occurred there in May 1980 (Fig. 12), and at least two had non-DC mechanisms. These events followed 2 years of volcanic unrest characterized by escalating seismic activity and surface deformation indicating magma-chamber inflation. Moment tensor inversions of different subsets of the available data conducted independently and using different methods all gave mechanisms that were similar and close to CLVDs. Any volumetric components were unresolvably small. The source processes probably involved tensile faulting at high fluid pressure, perhaps associated with dike intrusion. A M_S 5.6 earthquake similar in mechanism to the Long Valley earthquakes, though differently orientated, occurred near Tori Shima island, in the Izu-Bonin arc, on June 13, 1984. Because the earthquake was shallow, its full moment tensor could not be determined well, but the data were consistent with a mechanism close to a CLVD with a vertical symmetry axis. The seismic moment and source duration required intrusion of approximately 0.02 km^3 within 10–40 s (Kanamori et al. 1993).

Non-Double-Couple Earthquakes,

Fig. 13 Harvard centroid moment tensor mechanisms of earthquakes at Bardarbunga volcano, southeast Iceland, from Ekström (1994)

Bardarbunga volcano, beneath the Vatnajökull ice cap in Iceland, regularly generates non-DC earthquakes with M_W 5.2–5.6 ($M_0 = 8$ to 30×10^{16} Nm) (Ekström 1994). They typically have nearly vertical CLVD-like mechanisms. A particularly well-studied example that occurred in 1996 yielded a non-DC mechanism with a 67 % vertically oriented compensated linear vector dipole component, a 32 % DC component, and a statistically insignificant (2 %) volumetric contraction. They may result from slip on a ring fault and can be explained by activation of less than 55° of such a fault. Cone sheets, which dip inward, have the most favorable geometry (Fig. 13).

Earthquakes at Mines

Deep mine excavations perturb the stresses in the surrounding rocks, reducing some components from values initially of the order of 100 MPa practically to zero. The resulting stress differences can exceed the strength of competent rock and cause earthquakes (often called “rock bursts,” “coal bumps,” etc.). Seismic data show clearly that many earthquakes at mines have non-DC mechanisms, usually with predominantly dilatational radiation patterns, that are incompatible with shear faulting.

An M_L 3.5 earthquake on May 14, 1981, at the Gentry Mountain mine, Utah, coincided with the collapse of a large cavity at 200-m depth in the mine.

Well-recorded earthquakes occurring at the Coeur d’Alene mining district, Idaho, had dilatational P -wave polarities, consistent with cavity collapse.

A M_W 3.9 event occurred in the Crandall Canyon coal mine, Utah, August 6, 2007, in association with a gallery collapse that killed six miners and, later, three rescuers. Its focal mechanism is dominated by an implosive component, consistent with a shallow underground collapse (Dreger et al. 2008).

Many non-DC earthquakes occurred in association with the excavation of a 3.5-m-wide tunnel in unfractured, homogeneous granite at the Underground Research Laboratory in Manitoba, Canada (Feignier and Young 1992). Moment tensors computed for 33 earthquakes with M_W -2 to -4 include tensile, implosive, and shear mechanisms. Some were associated with breakout on the tunnel roof, and others occurred ahead of the active face.

Earthquakes located within 150 m of deep gold mines in the Witwatersrand, South Africa, had large volume decreases consistent with the partial collapse of mine galleries (McGarr 1992).

Fluid Injection

Fluids are injected into the shallow crust increasingly often for reasons such as increasing permeability within geothermal and hydrocarbon reservoirs by hydrofracturing, sequestration of CO₂, storing gas, and disposing of waste. Such injection often induces earthquakes, but they are not always monitored in detail. Nevertheless, in a number of well-studied cases non-DC source mechanisms have been observed (e.g., Baig and Urbancic 2010; Julian et al. 2010). Source types typically range from explosive to implosive dipoles. As underground fluid injections increase in importance over the coming decades, more detailed studies of the source mechanisms of the earthquakes induced may prove to be important for understanding the response of the Earth to such operations, project optimization and hazard mitigation.

Other Shallow Earthquakes

Real fault surfaces are not perfectly planar, and earthquakes on curved faults can, for some geometries, have non-DC mechanisms (Frohlich et al. 1989). Effects of this sort may account for the non-DC components observed in some large earthquakes, such as the 28-km deep M_S 7.8 event that occurred near Taiwan on November 14, 1986 (Zheng et al. 1995). The focal mechanism is inconsistent with shear faulting, but requires an implosive component. A similar, M 4.6 earthquake that occurred February 10, 1987, beneath the Kanto district, Japan. It had primarily dilatational compressional-wave polarities and was consistent with a conical nodal plane.

Deep-Focus Earthquakes

Earthquakes up to 700 hundred km deep occur in the mantle beneath subduction zones. The physical causes of deep earthquakes are not well understood. This is because minerals are expected to flow plastically at depths greater than about 30 km in normal areas. Processes that have been suggested to explain deep earthquakes include plastic instabilities, shear-induced melting, polymorphic phase transformations, and transformational faulting. Focal mechanisms can potentially shed light on this problem.

Volume changes in deep earthquakes are statistically unresolvable (less than 10 % of the seismic moment) (Kawakatsu 1991), indicating that polymorphic phase changes (section “[Rapid Polymorphic Phase Changes](#)”), play an insignificant role in deep earthquakes. Deep earthquakes do, however, have larger CLVD components than shallow earthquakes, and in some cases the sizes of the CLVD components increases systematically with depth and magnitude. The lack of large volume changes in deep earthquakes is compatible with complex shear faulting, and detailed waveform analysis resolves some deep non-DC earthquakes into DC subevents.

Glacial Earthquakes

Glaciers are subject to several kinds of sudden transient phenomena, apparently caused by diverse physical processes. Application of seismological analysis techniques to these events promises to provide fundamentally new types of data bearing on glacier dynamics and on understanding glaciers’ response to influences such as climate change (Ekström et al. 2006).

Earthquakes apparently caused by glacier surges or calving, even though they can be large ($M \geq 4.5$), were recognized on seismograms only recently, because they have source durations of the order of a minute or more and excite high-frequency seismic waves only weakly. The application of array-processing techniques to digital seismic data from the global network now enables us to detect dozens of large glacial earthquakes per year that previously went unnoticed. A particularly well-recorded event, of magnitude about 5, occurred in 1999 near the Dall glacier in the Denali range of Alaska, within a regional seismometer network and near a second, temporarily deployed, network. The low-frequency (~ 0.01 – 0.2 Hz) seismic waves are inconsistent with any moment-tensor mechanism, but agree well with those predicted for an approximately horizontal force directed in the direction of the glacier flow (Ekström et al. 2003). Seismic data from numerous other events, most of them near the margins of the Greenland icecap, are consistent with similar single-force mechanisms.

Most small ($M \geq -2.5$) icequakes in mountain glaciers have mechanisms describable by moment tensors, but they often differ greatly from DCs. Walter et al. (2009, 2010) recorded tens of thousands of events on Gornergletscher, in the Swiss Alps, on dense seismometer networks, and extended Dreger's waveform-inversion method, originally developed for earthquakes above magnitude 4, to frequencies approaching 1 KHz, in order to study the mechanisms of these microearthquakes. Most events had large explosive volumetric components, with source types close to those for opening tensile cracks. These included shallow events, probably representing crevasse opening, and events 100 m below the surface. Many shallow events were of a different type, equivalent to a DC combined with a volume decrease. A later study (Walter et al. 2010) of events near the base of the glacier found opening-crack mechanisms, but with inferred crack planes oriented horizontally.

Summary

A wide variety of processes can cause earthquake mechanisms to depart from the ideal DC force system that characterizes planar shear faulting in a homogeneous isotropic medium. These departures can be as extreme as unbalanced forces or torques associated with major landslides, glacial surges, or volcanic eruptions, or can be minor anomalies that are barely resolvable with the best data currently available. Studying non-DC earthquake mechanisms can be valuable for refining our knowledge of how faults work, for learning to understand and predict volcanic activity, for prospecting and exploiting geothermal energy and hydrocarbons, and for avoiding damage to civil and industrial infrastructure. Moreover, non-DC mechanisms are of direct value for monitoring mining and other industrial activities, particularly ones that involve fluid injection.

Introduction

Due to the extensive use of performance-based seismic design in earthquake engineering, nonlinear analysis has become an important method for evaluating the seismic performances of structures. In comparison with elastic analysis, nonlinear analysis is usually more complex and expensive. Nonlinear analysis generally involves

nonlinear static analysis (pushover) and nonlinear dynamic analysis in earthquake engineering. The nonlinearities mainly come from material nonlinearity, geometric nonlinearity, elemental nonlinearity, and contact nonlinearity. Only when these nonlinearities are considered correctly in the analysis models can the structural responses be reasonably predicted.

Material Nonlinearity

Most materials used in structural engineering exhibit nonlinear behavior, such as concrete, steel, and soil. For example, the deformation is not proportional to the load, and permanent plastic deformation remains after being unloaded. In addition to the elastic material constants (Young's modulus and Poisson's ratio), the yield criterion, the work hardening, and the flow rules are very essential to describe the nonlinear material behavior (Chen 2005).

The yield stress of a material is a measured stress level that separates the elastic and inelastic behavior of the material. The magnitude of the yield stress is generally obtained from the results of a uniaxial test. However, the stresses in a structure are usually multiaxial. A measurement of yielding for the multiaxial state of stress is called the yield criterion. For example, the Mohr-Coulomb criterion, the Buyukozturk criterion, and the Drucker-Prager criterion are common yield criteria for concrete, and the von Mises criterion is the widely used yield criterion for steel.

Isotropic hardening, kinematic hardening, and combined hardening are three typical work hardening rule types in civil engineering (Chen 2005). The isotropic work hardening rule assumes that, due to work hardening, the center of the yield surface remains stationary in the stress space and the size (radius) of the yield surface expands. In contrast, for the kinematic hardening rule, the yield surface does not change in size or shape, and the center of the yield surface can move in the stress space.

Yield stress and work hardening rules are two experimentally related phenomena that

characterize plastic material behavior. The flow rule is also essential in establishing the incremental stress-strain relationships for plastic material. The flow rule describes the differential changes in the plastic strain components as a function of the current stress state (Chen 2005). In most nonlinear analyses, the associated flow rule in which the direction of inelastic straining is normal to the yield surface is adopted.

Geometric Nonlinearity

There are two natural classes of geometric nonlinearities: the large displacement, small strain problem and the large displacement, large strain problem. For the large displacement, small strain problem, changes in the stress-strain law can be neglected, but the contributions from the nonlinear terms in the strain-displacement relations cannot be neglected. For the large displacement, large strain problem, the constitutive relation, which must be defined in the correct frame of reference, is transformed from this frame of reference to the one in which the equilibrium equations are written. Most of the geometric nonlinearities in structural engineering correspond to the large displacement, small strain problem; two typical examples are the $P-\Delta$ effect of a structure and the $P-\delta$ effect of a component. The total Lagrangian procedure can be used to describe the geometric nonlinearity in both the static and dynamic analyses. The equilibrium is expressed with the original undeformed state as the reference. The nonlinear analysis method should have the ability to address this geometric nonlinearity; if it does not have the ability, the structural capacity will be overestimated, leading to an unsafe design.

Elemental Nonlinearity

During the nonlinear analysis, the structural components may reach their load-carrying capacities and be out of work, at which point, the elemental nonlinearity occurs. To handle

Nonlinear Analysis and Collapse Simulation Using Serial Computation, Fig. 1 Example of a pushover analysis: (a) the load pattern, (b) the capacity curve, and (c) the typical failure mode

this problem, the elemental deactivation technology, in which the failed elements are deactivated when a specified elemental-failure criterion is satisfied, can be used (Lu et al. 2011, 2013). For example, the material-related failure criterion should be used to monitor the failure of structural elements. If the strain at any integration point exceeds the material failure criterion, the stress and the stiffness of this element are deactivated, which means that this element no longer contributes to the stiffness computation of the entire structure. The nodes that are connected to the deactivated element are simultaneously checked. A node is considered “isolated” when all its constituent elements are deactivated, which implies that this node contains zero stiffness in relation to the degrees of freedom (DOFs). Because the “isolated” nodes are more likely to cause convergence problems, all of the DOFs of the “isolated” nodes are removed from the global stiffness matrix.

Nonlinear Static Analysis

Nonlinear static analysis, which is commonly referred to as pushover analysis in earthquake engineering, enables the simple evaluation of the bearing of structural loads and the deformation capacities, as well as the evaluation of

the internal forces and deformations of components. This analysis method was first proposed by Freeman et al. (1975) to approximately assess the structural seismic performance using the seismic demand spectrum. During the pushover analysis, a given lateral load pattern is applied to the building and increases gradually to obtain the structural internal forces and displacements. Combined with the use of the seismic demand spectrum or the target displacement performance, the approximate seismic performance under the expected earthquake can be evaluated. As a simplified performance evaluation method, the following assumption should be complied: the deformation of the building is controlled by the first vibration mode, and this deformation pattern remains unchanged along the building height during the analysis process. Correspondingly, four types of load patterns are widely used in the pushover analysis, including the height-based load pattern, the fundamental mode-dominated load pattern, the SRSS-based load pattern, and the uniform load pattern.

Taking a simple frame structure (shown in Fig. 1a) as an example, the fiber-beam element (Lu et al. 2013) or plastic hinge model (Ibarra et al. 2005) can be used to simulate the nonlinear behavior of beams and columns. The inverted-triangle load pattern, which is a particular

Nonlinear Analysis and Collapse Simulation Using Serial Computation,

Fig. 2 Displacement responses at the MCE level

Nonlinear Analysis and Collapse Simulation Using Serial Computation,

Fig. 3 Typical collapse mode subjected to the El-Centro ground motion

pattern of the height-based load pattern, is applied to this building, resulting in the capacity curve. If the linear analysis is conducted, the capacity curve is the straight line in Fig. 1b. In addition, if only material nonlinearity is considered, the capacity curve is the solid line in Fig. 1b, which overestimates the load-carrying

capacity of the building. Correspondingly, if both the material and geometric nonlinearities are considered, the capacity curve is the dashed line in Fig. 1b, which better reflects the real seismic performance of the building. In addition, the initial collapse is predicted to occur in the middle column (shown in Fig. 1c).

Nonlinear Analysis and Collapse Simulation Using Serial Computation,
Fig. 4 Details of the collapse process

Nonlinear Dynamic Analysis

In comparison with the nonlinear static analysis, the nonlinear dynamic analysis, which has attracted more attention in recent years, exhibits a broader range of applications. Because nonlinear dynamic analysis is directly based on the structural dynamic equation, the displacement, velocity, and acceleration of each story of a building and the internal forces, cracking, and yielding of the individual structural components of a building can be obtained

at any moment. The analysis also reflects the characteristics of ground motion, including amplitude and duration. Therefore, this method has been widely used in many building codes for the seismic evaluation of buildings with unusual configurations or of special importance. However, the structural response may be very sensitive to the characteristics of the individual ground motion used as the seismic input; therefore, seven pairs of ground motion records, at least three pairs, are suggested in most building codes as the basic seismic input to

achieve a reliable estimation of the mean structural responses. In addition, the damping effect must be considered in the dynamic analysis. Rayleigh damping is one of the most effective means of deriving a suitable damping matrix, which can be expressed in proportion to the structural mass matrix and the initial or current tangent stiffness matrix (Clough and Penzien 1975). Subsequently, based on the nonlinear detailed finite element model and appropriate ground motion records, the seismic performance of the building at various seismic hazard levels can be predicted and evaluated, as well as the potential collapse modes.

Taking an actual super-tall building, for example, the nonlinear dynamic analysis of the Shanghai Tower, with the total height of 632 m, is described in the following. The beams and columns are simulated by fiber-beam elements, the shear walls are simulated by multilayer shell elements, and elemental deactivation technology is used to simulate the components failure (Lu et al. 2011). The fundamental period is approximately 9.8 s. The displacement responses under four widely used ground motion records at the maximum considered earthquake (MCE) level and the typical potential collapse mode under the extreme earthquake are shown in Figs. 2 and 3, respectively.

The details of the collapse process are illustrated in Fig. 4. When $t = 2.58$ s, some coupling beams in the core tube begin to fail, and the flange wall of the core tube at the bottom of Zone 7 is crushed. This crushing is caused by the changes in the layout of the openings in the core tube between Zones 6 and 7, which results in sudden changes in the stiffness and the stress concentration. When $t = 3.90$ s, the shear wall at the bottom of Zone 5 begins to fail because the cross section of the core tube changes from Zone 4 to Zone 5, as shown in Fig. 4b. When $t = 5.88$ s, over 50 % of the shear walls at the bottom of Zone 5 fail, and the internal forces are redistributed to the remaining components. The vertical and horizontal loads in the mega-columns gradually increase and reach their load capacities. Subsequently, the mega-columns begin to fail. When $t = 6.18$ s, the core tube and mega-columns in Zone 5 are completely destroyed, and the collapse begins to propagate

throughout the entire structure. Obviously, Zone 5 is a typical potentially weak part.

Summary

To improve the structural seismic safety of new and existing buildings is always the most important objective in earthquake engineering. Based on the appropriate numerical models, including the models of the material nonlinearity, geometric nonlinearity, and elemental nonlinearity, the nonlinear analysis, especially the nonlinear dynamic analysis, is currently one of the best tools for the prediction of structural responses at varying seismic hazard levels. In addition, the potential collapse modes and the corresponding weak parts can be predicted using a collapse simulation, which provides a better understanding of the collapse mechanism of buildings and contributes to the further development of both the optimum design and the structural health monitoring methodologies.

Flexural–torsional analysis; Geometrically nonlinear dynamic analysis; Secondary torsional moment; Shear deformation warping

Introduction

In engineering practice beam-like continuous systems are encountered in the vast majority of structural engineering projects (Fig. 1). The term “beam-like” refers to these structural members, one dimension of which is significantly larger than the other two. As far as the analysis of such members is concerned, many modeling strategies can be applied (based mainly on finite elements); however, it is common knowledge that, especially in cases of complicated beam assemblages, beam theories are a very attractive modeling approach. Beam elements are practical and computationally efficient and offer better insight of the structural phenomena since they permit their isolation and their independent investigation. Furthermore, due to easy parameterization of all necessary data, beam elements are more convenient for parametric analyses than more refined models which, in most cases, require the construction of multiple models.

Apart from static external loading, structures are very often subjected to external loading, the magnitude, the direction, and the position of which vary with time, i.e., dynamic external loading. Such cases of loading include seismic excitations, excitations due to wind conditions, vibrations induced by large mechanical devices, impact loading due to explosions, etc. The aforementioned arbitrary external dynamic loading leads to the formulation of the flexural–torsional

vibration problem. The complexity of this problem increases significantly in the case the cross section’s centroid does not coincide with its shear center (asymmetric beams). Furthermore, when arbitrary torsional boundary conditions are applied either at the edges or at any other interior point of a beam due to construction requirements, the beam under the action of general twisting loading is led to nonuniform torsion. Moreover, since requirement of weight saving is a major aspect in the design of structures, thin-walled elements of arbitrary cross section and low flexural and/or torsional stiffness are extensively used. Treating displacements and angles of rotation of these elements as being small leads in many cases to inadequate prediction of the dynamic response; hence, the occurring nonlinear effects should be taken into account. This can be achieved by retaining the nonlinear terms in the strain–displacement relations (finite displacement–small strain theory).

When the displacement components of a member are small, a wide range of linear analysis tools, such as modal analysis, can be used, and some analytical results are possible. As these components become larger, the induced geometrical nonlinearities result in effects that are not observed in linear systems. When finite displacements are considered, the flexural–torsional dynamic analysis of beams becomes much more complicated, leading to the formulation of coupled and nonlinear flexural, torsional, and axial equations of motion. The analysis of these systems becomes even more complicated when shear deformation effect in flexure and secondary torsional moment deformation effect (STMDE) in torsion, which are significant in many cases (e.g., short beams, beams of box-shaped cross sections, folded structural members, beams made of materials weak in shear, etc.), are taken into account.

In section “[Nonlinear Flexural Dynamic Analysis of Beams with Shear Deformation Effect](#)” of this chapter, the geometrically nonlinear dynamic flexural analysis of homogeneous prismatic beam members taking into account shear deformation and rotary inertia effects (Timoshenko beam theory) is presented. The differential equations of

Nonlinear Dynamic Seismic Analysis, Fig. 1 Structural engineering projects composed by beam structural members

motion governing free or forced vibrations of Timoshenko beams are formulated employing the principle of virtual work. In order to be able to examine the flexural problem independently (i.e., excluding torsional response) and without loss of generality, the case of beams of arbitrary doubly symmetric cross sections subjected to torsionless bending (external transverse loading passes through the shear center of the cross section which coincides with its centroid) is examined. For a detailed review of the relevant literature, the reader is referred to the study of Sapountzakis and Dourakopoulos (2009a, b).

Since very often beam members under arbitrary external dynamic loading develop torsional response, the rigorous dynamic analysis of nonuniform torsion of beams in the nonlinear range is necessary. In section “[Nonlinear Torsional Dynamic Analysis of Beams with Secondary Torsional Moment Deformation Effect \(STMDE\)](#)” of this chapter, the geometrically nonlinear dynamic torsional analysis of homogeneous prismatic beam members taking into account STMDE (analogy with Timoshenko beam theory) is presented. The differential equations of motion governing free or forced vibrations of beams under nonuniform torsion are formulated employing the principle of virtual work. Similarly with section “[Nonlinear Flexural Dynamic Analysis of Beams with Shear Deformation Effect](#),” the case of beams of arbitrary doubly symmetric cross sections subjected to twisting and/or warping moments is examined.

For a detailed review of the relevant literature, the reader is referred to the studies of Sapountzakis and Tsipiras (2010a, b, c).

Finally, in order to highlight the significant coupling between flexure and torsion when displacements and rotations become large, in section “[Nonlinear Flexural–Torsional Dynamic Analysis of Beams of Arbitrary Cross Section](#),” the formulation for the geometrically nonlinear flexural–torsional dynamic analysis of prismatic beams is analyzed. In this section, the most general case is examined by considering arbitrary thin- or thick-walled cross sections possessing no axis of symmetry. The beam may undergo moderately large deflections and twisting rotations, under the most general boundary conditions. The beam is subjected to arbitrarily distributed or concentrated transverse loading, which can be applied on any arbitrary point of the lateral surface of the beam, to bending moments, as well as to twisting and/or axial loading. For a detailed review of the relevant literature, the reader is referred to the study of Sapountzakis and Dikaros (2011).

Nonlinear Flexural Dynamic Analysis of Beams with Shear Deformation Effect

Statement of the Problem

Let us consider a prismatic beam of length L of doubly symmetric cross section of area A , occupying the multiply connected region Ω of the y, z

Nonlinear Dynamic Seismic Analysis, Fig. 2 Prismatic beam in axial–flexural loading (a) with an arbitrary doubly symmetric cross section occupying the two-dimensional region Ω (b)

plane and is bounded by the curve $\Gamma = \cup_{j=1}^K \Gamma_j$, which is piecewise smooth, i.e., it may have a finite number of corners (Fig. 2). The material of the beam is considered to be homogeneous, isotropic, and linearly elastic with modulus of elasticity E , shear modulus G , Poisson ratio ν , and mass density ρ . In Fig. 2b, $Cxyz \equiv CXYZ$ is the principal bending system of axes passing through the cross section's centroid C (coinciding with the shear center S). The beam is subjected to the combined action of the arbitrarily distributed or concentrated time-dependent axial loading $p_x = p_x(x, t)$; transverse loading $p_y = p_y(x, t)$, $p_z = p_z(x, t)$ acting in the y, z directions, respectively; and bending moments $m_y = m_y(x, t)$, $m_z = m_z(x, t)$ along y, z axes, respectively.

Under the action of the aforementioned loading, the beam does not develop twisting rotation, and the displacement field taking into account shear deformation effect can be written as

$$\bar{u}(x, y, z, t) = u(x, t) - y\theta_z(x, t) + z\theta_y(x, t) \quad (1a)$$

$$\bar{v}(x, t) = v(x, t) \quad (1b)$$

$$\bar{w}(x, t) = w(x, t) \quad (1c)$$

where $\bar{u}, \bar{v}, \bar{w}$ are the displacement components of an arbitrary point of the cross section with respect to $Cxyz$; $u(x, t)$, $v(x, t)$, $w(x, t)$ are the corresponding components of the centroid, and $\theta_y(x, t)$, $\theta_z(x, t)$ are the angles of rotation due to bending of the cross section which do not

coincide with the deflection slopes (w' , v'). Employing the strain–displacement relations of the Green–Lagrange strain tensor (Rothert and Gensichen 1987; Ramm and Hofmann 1995), the strain components can be obtained as

$$\begin{aligned} \varepsilon_{xx} &= \frac{\partial \bar{u}}{\partial x} + \frac{1}{2} \left[\left(\frac{\partial \bar{u}}{\partial x} \right)^2 + \left(\frac{\partial \bar{v}}{\partial x} \right)^2 + \left(\frac{\partial \bar{w}}{\partial x} \right)^2 \right] \\ &\approx \frac{\partial \bar{u}}{\partial x} + \frac{1}{2} \left[\left(\frac{\partial \bar{v}}{\partial x} \right)^2 + \left(\frac{\partial \bar{w}}{\partial x} \right)^2 \right] \end{aligned} \quad (2a)$$

$$\begin{aligned} \gamma_{xz} &= \frac{\partial \bar{w}}{\partial x} + \frac{\partial \bar{u}}{\partial z} + \left(\frac{\partial \bar{u}}{\partial x} \frac{\partial \bar{u}}{\partial z} + \frac{\partial \bar{v}}{\partial x} \frac{\partial \bar{v}}{\partial z} + \frac{\partial \bar{w}}{\partial x} \frac{\partial \bar{w}}{\partial z} \right) \\ &\approx \frac{\partial \bar{w}}{\partial x} + \frac{\partial \bar{u}}{\partial z} + \left(\frac{\partial \bar{v}}{\partial x} \frac{\partial \bar{v}}{\partial z} + \frac{\partial \bar{w}}{\partial x} \frac{\partial \bar{w}}{\partial z} \right) \end{aligned} \quad (2b)$$

$$\begin{aligned} \gamma_{xy} &= \frac{\partial \bar{v}}{\partial x} + \frac{\partial \bar{u}}{\partial y} + \left(\frac{\partial \bar{u}}{\partial x} \frac{\partial \bar{u}}{\partial y} + \frac{\partial \bar{v}}{\partial x} \frac{\partial \bar{v}}{\partial y} + \frac{\partial \bar{w}}{\partial x} \frac{\partial \bar{w}}{\partial y} \right) \\ &\approx \frac{\partial \bar{v}}{\partial x} + \frac{\partial \bar{u}}{\partial y} + \left(\frac{\partial \bar{v}}{\partial x} \frac{\partial \bar{v}}{\partial y} + \frac{\partial \bar{w}}{\partial x} \frac{\partial \bar{w}}{\partial y} \right) \end{aligned} \quad (2c)$$

$$\varepsilon_{yy} = \varepsilon_{zz} = \gamma_{yz} = 0 \quad (2d)$$

where it has been assumed that for moderate displacements $(\partial \bar{u} / \partial x)^2 \ll (\partial \bar{u} / \partial x)$, $(\partial \bar{u} / \partial x)(\partial \bar{u} / \partial z) \ll (\partial \bar{u} / \partial x) + (\partial \bar{u} / \partial z)$, $(\partial \bar{u} / \partial y) \ll (\partial \bar{u} / \partial x) + (\partial \bar{u} / \partial y)$. Substituting the displacement components Eq. 1 to the

strain–displacement relations Eq. 2, the strain components are written as

$$\varepsilon_{xx} = u' + z\theta'_y - y\theta'_z + \frac{1}{2}(v'^2 + w'^2) \quad (3a)$$

$$\gamma_{xy} = v' - \theta_z \quad (3b)$$

$$\gamma_{xz} = w' + \theta_y \quad (3c)$$

It is noted that within the Euler–Bernoulli theory context, it holds that $\theta_z = v'$, $\theta_y = -w'$ (the cross section remains perpendicular to the deformed axis); hence, shear strain components Eqs. 3b and 3c vanish. Considering strains to be small and employing the second Piola–Kirchhoff stress tensor, the nonvanishing stress components are defined in terms of the strain ones as

$$\begin{Bmatrix} S_{xx} \\ S_{xy} \\ S_{xz} \end{Bmatrix} = \begin{bmatrix} E^* & 0 & 0 \\ 0 & G & 0 \\ 0 & 0 & G \end{bmatrix} \begin{Bmatrix} \varepsilon_{xx} \\ \gamma_{xy} \\ \gamma_{xz} \end{Bmatrix} \quad (4)$$

where E^* is obtained from Hooke's stress–strain law as $E^* = E(1 - \nu)/(1 + \nu)(1 - 2\nu)$. If the assumption of plane stress condition is made, the above expression is reduced in $E^* = E/(1 - \nu^2)$ (Vlasov 1963), while in beam formulations, E is frequently considered instead of E^* ($E^* \approx E$). This last consideration has been followed throughout this study, while any other reasonable value of E^* could be used without any difficulty. Substituting Eq. 3 into Eq. 4, the nonvanishing stress components are obtained as

$$S_{xx} = E \left[u' + z\theta'_y - y\theta'_z + \frac{1}{2}(v'^2 + w'^2) \right] \quad (5a)$$

$$S_{xy} = G \cdot (v' - \theta_z) \quad (5b)$$

$$S_{xz} = G \cdot (w' + \theta_y) \quad (5c)$$

In order to establish the nonlinear equations of motion, the principle of virtual work

$$\delta W_{\text{int}} + \delta W_{\text{mass}} = \delta W_{\text{ext}} \quad (6)$$

where

$$\delta W_{\text{int}} = \int_V (S_{xx}\delta\varepsilon_{xx} + S_{xy}\delta\gamma_{xy} + S_{xz}\delta\gamma_{xz})dV \quad (7a)$$

$$\delta W_{\text{mass}} = \int_V \rho(\ddot{u}\delta u + \ddot{v}\delta v + \ddot{w}\delta w)dV \quad (7b)$$

$$\delta W_{\text{ext}} = \int_F (t_x\delta\bar{u} + t_y\delta\bar{v} + t_z\delta\bar{w})dF \quad (7c)$$

under a total Lagrangian formulation is employed. In the above equations, $\delta(\cdot)$ and $(\cdot)$ denote virtual quantities and derivatives with respect to time, respectively, V is the volume of the beam in the initial (undeformed) configuration, F is the lateral surface of the beam in the initial configuration including the end cross sections, and t_x , t_y , t_z are the components of the traction vector with respect to the undeformed surface of the beam. Moreover, the stress resultants of the beam are given as

$$N = \int_{\Omega} S_{xx}dx \quad (8a)$$

$$M_y = \int_{\Omega} S_{xx}zdx \quad (8b)$$

$$M_z = - \int_{\Omega} S_{xx}ydx \quad (8c)$$

$$Q_y = \int_{\Omega} S_{xy}dx \quad (8d)$$

$$Q_z = \int_{\Omega} S_{xz}dx \quad (8e)$$

Substituting the expressions of the stress components Eq. 5 into Eq. 8, the stress resultants are obtained as

$$N = EA \left[u' + \frac{1}{2}(v'^2 + w'^2) \right] \quad (9a)$$

$$M_y = EI_y \theta'_y \quad (9b)$$

$$M_z = EI_z \theta'_z \quad (9c)$$

$$Q_y = GA_y \gamma_{xy} = GA_y (v' - \theta_z) \quad (9d)$$

$$Q_z = GA_z \gamma_{xz} = GA_z (w' + \theta_y) \quad (9e)$$

where A , I_y , I_z are the cross-sectional area and the principal moments of inertia of the cross section given as

$$A = \int_{\Omega} dx \quad (10a)$$

$$I_y = \int_{\Omega} z^2 dx \quad (10b)$$

$$I_z = \int_{\Omega} y^2 dx \quad (10c)$$

and GA_y , GA_z are the shear rigidities of the Timoshenko theory, where

$$A_y = \kappa_y A = \frac{1}{a_y} A \quad (11a)$$

$$A_z = \kappa_z A = \frac{1}{a_z} A \quad (11b)$$

are the shear areas with respect to y , z axes, respectively, with κ_y , κ_z being the shear correction factors and a_y , a_z being the shear deformation coefficients.

Employing Eq. 8 and substituting Eqs. 1, 3, and 9 to 6, the differential equations of motion are derived as

$$-EA(u'' + w'w'' + v'v'') + \rho \zeta \ddot{u} = p_x \quad (12a)$$

$$-(Nv')' + \rho \zeta \ddot{v} - GA_y(v'' - \theta'_z) = p_y \quad (12b)$$

$$-EI_z \theta''_z + \rho I_z \ddot{\theta}_z - GA_y(v' - \theta_z) = m_z \quad (12c)$$

$$-(Nw')' + \rho \zeta \ddot{w} - GA_z(w'' + \theta'_y) = p_z \quad (12d)$$

$$-EI_y \theta''_y + \rho I_y \ddot{\theta}_y + GA_z(w' + \theta_y) = m_y \quad (12e)$$

Combining Eqs. 12b and 12c with 12d and 12e in order to eliminate θ_y , θ_z , the following differential equations are derived

$$\begin{aligned} EI_z v'''' - \left(\frac{EI_z}{G \zeta_y} \rho \zeta + \rho I_z \right) \ddot{v}'' + \rho \zeta \ddot{v} + \frac{EI_z}{GA_y} (Nv')''' - (Nv')' \\ - \frac{\rho I_z}{GA_y} \left(\frac{\partial^2 (Nv')'}{\partial t^2} - \rho A \ddot{v} \right) = p_y - \frac{EI_z}{GA_y} p_y'' + \frac{\rho I_z}{GA_y} \ddot{p}_y - m'_z \end{aligned} \quad (13a)$$

$$\begin{aligned} EI_y w'''' - \left(\frac{EI_y}{G \zeta_z} \rho A + \rho I_y \right) \ddot{w}'' + \rho \zeta \ddot{w} + \frac{EI_y}{GA_z} (Nw')''' - (Nw')' \\ - \frac{\rho I_y}{GA_z} \left(\frac{\partial^2 (Nw')'}{\partial t^2} - \rho A \ddot{w} \right) = p_z - \frac{EI_y}{GA_z} p_z'' + \frac{\rho I_y}{GA_z} \ddot{p}_z + m'_y \end{aligned} \quad (13b)$$

In Eqs. 12a and 13, the quantities p_x , p_y , p_z , m_z , m_y (external axial loading, transverse loading, and bending moments along each direction, respectively) constitute the externally applied time-dependent loading along the beam (Fig. 2a) and arise (through the principle of virtual work) from the externally applied traction vectors t_x , t_y , t_z . Ignoring time derivatives of fourth order from the above equations (Thomson 1981), the following governing differential equations are derived as

$$-EA(u'' + w'w'' + v'v'') + \rho \zeta \ddot{u} = p_x \quad (14a)$$

$$\begin{aligned} EI_z v'''' - \rho I_z \left(\frac{Ea_y}{G} + 1 \right) \ddot{v}'' + \rho \zeta \ddot{v} + \frac{EI_z}{GA_y} (Nv')''' - (Nv')' \\ - \frac{\rho I_z}{GA_y} \frac{\partial^2 (Nv')'}{\partial t^2} = p_y - \frac{EI_z}{GA_y} p_y'' + \frac{\rho I_z}{GA_y} \ddot{p}_y - m'_z \end{aligned} \quad (14b)$$

$$\begin{aligned} EI_y w'''' - \rho I_y \left(\frac{Ea_z}{G} + 1 \right) \ddot{w}'' + \rho \zeta \ddot{w} + \frac{EI_y}{GA_z} (Nw')''' - (Nw')' \\ - \frac{\rho I_y}{GA_z} \frac{\partial^2 (Nw')'}{\partial t^2} = p_z - \frac{EI_y}{GA_z} p_z'' + \frac{\rho I_y}{GA_z} \ddot{p}_z + m'_y \end{aligned} \quad (14c)$$

The stress resultants and bending rotations are expressed as

$$M_z = EI_z v'' + \frac{EI_z}{GA_y} [p_y - \rho A \ddot{v} + (Nv')'] \quad (15a)$$

$$M_y = -EI_y w'' + \frac{EI_y}{GA_z} [\rho A \ddot{w} - p_z - (Nw')'] \quad (15b)$$

$$Q_y = -EI_z v''' - \frac{EI_z}{GA_y} \left[p'_y - \rho A \ddot{v}' + (Nv')'' \right] + \rho I_z \ddot{\theta}_z - m_z \quad (15c)$$

$$Q_z = -EI_y w''' + \frac{EI_y}{GA_z} \left[\rho A \ddot{w}' - p'_z - (Nw')'' \right] - \rho I_y \ddot{\theta}_y + m_y \quad (15d)$$

$$\theta_z = v' - \frac{Q_y}{GA_y} \quad (15e)$$

$$\theta_y = -w' + \frac{Q_z}{GA_z} \quad (15f)$$

The above equations are also subjected to the pertinent boundary conditions of the problem which are given as

$$a_1 u(x, t) + \alpha_2 N(x) = \alpha_3 \quad (16a)$$

$$\beta_1 v(x, t) + \beta_2 R_y^b(x) = \beta_3 \quad (16b)$$

$$\bar{\beta}_1 \theta_z(x, t) + \bar{\beta}_2 M_z^b(x) = \bar{\beta}_3 \quad (16c)$$

$$\gamma_1 w(x, t) + \gamma_2 R_z^b(x) = \gamma_3 \quad (16d)$$

$$\bar{\gamma}_1 \theta_y(x, t) + \bar{\gamma}_2 M_y^b(x) = \bar{\gamma}_3 \quad (16e)$$

at the beam ends $x = 0, L$, where $a_i, \beta_i, \gamma_i, \bar{\beta}_i, \bar{\gamma}_i$ $i = 1, 2, 3$ are known time-dependent functions. The boundary conditions Eq. 16 are the most general boundary conditions for the problem at hand, including also the elastic support. It is apparent that all types of the conventional boundary conditions (clamped, simply supported, free, or guided edge) can be derived from Eq. 16 by specifying appropriately the functions $a_i, \beta_i, \gamma_i, \bar{\beta}_i, \bar{\gamma}_i$ (e.g., for a clamped edge, it is $\alpha_1 = \beta_1 = \bar{\beta}_1 = \gamma_1 = \bar{\gamma}_1 = 1, \alpha_2 = \alpha_3 = \beta_2 = \beta_3 = \gamma_2 = \gamma_3 = \bar{\beta}_2 = \bar{\beta}_3 = \bar{\gamma}_2 = \bar{\gamma}_3 = 0$). In Eq. 16, the reaction forces R_y^b, R_z^b ; bending moments M_z^b, M_y^b ; and the angles of bending rotations θ_y, θ_z at the beam ends ignoring the inertia terms are written as

$$R_y^b = Nv' - EI_z v''' - \frac{EI_z}{GA_y} Nv''' \quad (17a)$$

$$R_z^b = Nw' - EI_y w''' - \frac{EI_y}{GA_z} Nw''' \quad (17b)$$

$$M_z^b = EI_z v'' + \frac{EI_z}{GA_y} Nv'' \quad (17c)$$

$$M_y^b = -EI_y w'' - \frac{EI_y}{GA_z} Nw'' \quad (17d)$$

$$\theta_y^b = -w' - \frac{EI_y}{G^2 A_z^2} Nw''' - \frac{EI_y}{GA_z} w''' \quad (17e)$$

$$\theta_z^b = v' + \frac{EI_z}{G^2 A_y^2} Nv''' + \frac{EI_z}{GA_y} v''' \quad (17f)$$

In case of nonzero initial conditions, the following relations are valid for $t = 0$

$$u(x, 0) = \bar{u}_0(x) \quad (18a)$$

$$\dot{u}(x, 0) = \dot{\bar{u}}_0(x) \quad (18b)$$

$$v(x, 0) = \bar{v}_0(x) \quad (18c)$$

$$\dot{v}(x, 0) = \dot{\bar{v}}_0(x) \quad (18d)$$

$$w(x, 0) = \bar{w}_0(x) \quad (18e)$$

$$\dot{w}(x, 0) = \dot{\bar{w}}_0(x) \quad (18f)$$

$$\theta_z(x, 0) = \bar{\theta}_{z0}(x) \quad (18g)$$

$$\dot{\theta}_z(x, 0) = \dot{\bar{\theta}}_{z0}(x) \quad (18h)$$

$$\theta_y(x, 0) = \bar{\theta}_{y0}(x) \quad (18i)$$

$$\dot{\theta}_y(x, 0) = \dot{\bar{\theta}}_{y0}(x) \quad (18j)$$

Applications

Free Vibrations of Hinged Beam of Rectangular Cross Section

In order to examine the influence of shear deformation on the free vibrations of beams in the

Nonlinear Dynamic Seismic Analysis, Table 1 Material properties, geometric, inertia constants, and shear deformation coefficients of the rectangular cross section of application section “Free Vibrations of Hinged Beam of Rectangular Cross Section”

$E = 70 \text{ GPa}$	$G = 27 \text{ GPa}$
$\rho = 2.7 \text{ tn/m}^3$	$A = 150 \times 10^{-6} \text{ m}^2$
$I_y = 7,812.5 \times 10^{-12} \text{ m}^4$	$I_z = 450 \times 10^{-12} \text{ m}^4$
$a_y = 1.74$	$a_z = 1.20$

geometrically nonlinear range, a hinged beam of a $25 \times 6 \text{ mm}$ rectangular cross section subjected to free vibrations is studied. It is worth here mentioning that the axially immovable ends lead to the development of axial loading along the beam as deflections increase. The employed initial conditions are represented by the following expression $w(x, 0) = w_{\max} \sin(\pi x/L)$ where $w_{\max}$ is the central beam deflection. In Table 1, the material properties, the geometric and inertia constants, and the shear deformation coefficients of the examined cross section are presented.

In Fig. 3, the obtained results of the period ratios T/T_0 , at various amplitude ratios $w_{\max}/r$ for three different cases of beam slenderness L/r , as obtained from the numerical solution of the initial-boundary value problem Eqs. 14, 16, and 18 using analog equation method (AEM) and boundary element method (BEM)-based techniques (Sapountzakis and Dourakopoulos 2009a, b), are presented taking into account or ignoring shear deformation effect. T denotes the period of free vibration obtained by nonlinear analysis including rotary inertia and taking into account or ignoring shear deformation effect, T_0 is the corresponding period of the linear vibration ignoring both rotary inertia and shear deformation effect, and $r = \sqrt{I_y/A}$ is the radius of gyration about y axis. The obtained results are compared with the corresponding ones available in the study of Foda (1999) obtained by a multiple scales procedure. In Table 2 the ratios of the nonlinear frequency ω_{NL} over the linear one ω_L at various amplitude ratios $w_{\max}/r$ and slenderness L/r , obtained by AEM, are presented as compared with those obtained from a finite element solution employing polynomial expressions for the displacement components (Rao et al. 1976).

From this table the convergence of both methods can be observed. Moreover, from the above figure and table, the increment of vibration frequency with the increment of deflections can be observed due to the fact that axially immovable ends induce tensile forces to the beam, thus increasing its stiffness.

Free Vibrations of Beam with Very Flexible Boundary Conditions

In this application the free vibrations of Timoshenko beams with very flexible boundary conditions is examined, since in this case the natural frequencies and the corresponding modeshapes are highly sensitive to the effects of shear deformation and rotary inertia (Aristizabal-Ochoa 2004). Thus, the linear free vibration analysis of pinned-free beams of length $L = 5.0 \text{ m}$ of various cross sections is examined ($\rho = 2.40 \text{ tn/m}^3$, $E = 25.42 \text{ GPa}$, $G = 11.05 \text{ GPa}$). In Table 3 the geometric and inertia constants as well as the shear correction factors of the examined cross sections are presented ($\kappa = 1/\alpha$). The differential equations for the linear free vibrations of this special case can be obtained by Eq. 14 for zero axial stress resultant and external force as

$$EI_z v'''' - \rho I_z \left(\frac{Ea_y}{G} + 1 \right) \ddot{v}'' + \rho \zeta \ddot{v} = 0 \quad (19a)$$

$$EI_y w'''' - \rho I_y \left(\frac{Ea_z}{G} + 1 \right) \ddot{w}'' + \rho A \ddot{w} = 0 \quad (19b)$$

The boundary conditions for the examined case can be derived by Eq. 16 as

$$v(0, t) = w(0, t) = 0 \quad (20a)$$

$$M_y(0, t) = M_z(0, t) = 0 \quad (20b)$$

$$V_y(L, t) = V_z(L, t) = 0 \quad (20c)$$

$$M_y(L, t) = M_z(L, t) = 0 \quad (20d)$$

In Table 4 the first three natural frequencies of the pinned-free Timoshenko beams of various cross sections and in Fig. 4 the corresponding modeshapes for the cross section with web

T_z	0.01019	0.00911	0.01051	0.00958

and the periods T_y, T_z of the first cycle are presented for the aforementioned cases of analysis, taking into account or ignoring shear deformation effect. From this figure and table, the influence of geometrical nonlinearity can be observed reducing the magnitude of deflections and the period of vibrations due to axially immovable ends which lead to the development of axial forces, thus increasing the stiffness of the beam. Shear deformation effect is also

apparent increasing both the maximum central transverse displacements (especially in z direction) and the calculated periods of the first cycle of motion.

Forced Vibrations or Beam of Hollow Rectangular Cross Section Subjected to Axial Compressive Load

In order to further investigate the influence of geometrical nonlinearity on the response of Timoshenko beams, the nonlinear dynamic analysis of a clamped-rolled beam of length $l = 3.0$ m, having a hollow rectangular cross section ($E = 210$ GPa, $\nu = 0.3$, $\rho = 7.85 \text{ tn/m}^3$) subjected to the suddenly applied uniformly distributed loads $p_x(t) = -250$ kN/m, $p_y(t) = -150$ kN/m, $p_z(t) = -150$ kN/m and concentrated axial load $P_x(t) = -500$ kN at the rolled end ($t \geq 0$), as is shown in Fig. 7, has been studied.

In Fig. 8, the time histories of the central transverse displacements $v_{l/2}, w_{l/2}$ of the beam performing either a linear or a nonlinear analysis are presented taking into account or ignoring shear deformation effect. Moreover, in Table 6 the maximum values of the central deflections

$a_z = 1.766$

$a_y = 3.664$

Nonlinear Dynamic Seismic Analysis, Fig. 8 Time histories of central deflections along directions $y(v_{L/2})$, $z(w_{L/2})$ of the beam of application section “Forced Vibrations or

Beam of Hollow Rectangular Cross Section Subjected to Axial Compressive Load”

$w_{\max}$, $w_{\min}$ and the periods T_y , T_z of the first cycle are presented for the aforementioned cases of analysis, including or ignoring shear deformation effect. In all of the aforementioned cases, rotary inertia has been taken into account. From the obtained results, the influence of

geometrical nonlinearity is apparent, increasing the magnitude of kinematical components due to compressive loading, while the influence of shear deformation effect is also intense leading to further increment of the kinematical components.

Nonlinear Torsional Dynamic Analysis of Beams with Secondary Torsional Moment Deformation Effect (STMDE)

Statement of the Problem

The prismatic beam of doubly symmetric cross section described in section “Statement of the Problem” is examined and is subjected to the combined action of the arbitrarily distributed or concentrated time-dependent conservative axial load $p_x(x, t)$, twisting $m_t = m_t(x, t)$, and warping $m_w = m_w(x, t)$ moments acting in the x direction (Fig. 9a), while its ends are subjected to the most general boundary conditions with respect to the axial displacement, the angle of twist, and warping intensity. The beam can be twisted freely

about the longitudinal axis and its flexural behavior is not examined. The analysis is carried out with respect to the coordinate system $Sxyz$, the longitudinal axis Sx of which passes through the cross sections’ shear center. It is noted that due to the fact that the cross section is a doubly symmetric one, the shear center of the cross section coincides with the centroid (Fig. 9b).

Assuming that the cross section maintains its shape during deformation (no distortional effects), considering that the points of the cross section follow a circular trajectory around axis Sx , and considering twisting rotations to be large and taking into account STMDE effect, the displacement field of the beam is written as

$$\begin{aligned} \bar{u}(x, y, z, t) = & u(x, t) + (\theta_x^P(x, t))' \phi_S^P(y, z) \\ & - [(\theta_x^P(x, t))' - \theta_x'(x, t)] [\phi_S^P(y, z) + \phi_S^S(x, y, z, t)] \end{aligned} \quad (21a)$$

$$\bar{v}(x, y, z, t) = -z \sin \theta_x(x, t) - y(1 - \cos \theta_x(x, t)) \quad (21b)$$

$$\bar{w}(x, y, z, t) = y \sin \theta_x(x, t) - z(1 - \cos \theta_x(x, t)) \quad (21c)$$

In Eq. 21, apart from the “average” axial displacement $u(x, t)$ of the cross section defined in section “Nonlinear Flexural Dynamic Analysis of Beams with Shear Deformation Effect,” $\theta_x^P(x, t)$, $\theta_x(x, t)$ denote the primary part and the total angle

Nonlinear Dynamic Seismic Analysis, Table 6 Periods $T_y, T_z(s)$ of the first cycle and maximum central displacements $v_{\max}(m), w_{\max}(m)$ of the beam of application section “Forced Vibrations of Beam of Hollow Rectangular Cross Section Subjected to Axial Compressive Load”

Nonlinear Dynamic Seismic Analysis, Fig. 9 Prismatic beam of an arbitrarily shaped doubly symmetric constant cross section occupying region Ω (a) subjected to axial and torsional loading (b)

of twist, respectively; ϕ_S^P , ϕ_S^S are the primary and secondary warping functions with respect to the shear center S . Considering the “average” axial displacement and the warping displacements of the cross section to be small, strain components Eq. 2 and stress–strain relationship Eq. 4 are once again employed to derive the nonvanishing stress components of the second Piola–Kirchhoff stress tensor as

$$S_{xx} = E \left[u' + (\theta_x^P)'' \phi_S^P + \frac{1}{2} (y^2 + z^2) (\theta_x')^2 \right] \quad (22a)$$

$$S_{xy} = \underbrace{G \theta_x' \left(\frac{\partial \phi_S^P}{\partial y} - z \right)}_{\text{primary}} + \underbrace{G \left((\theta_x^P)' - \theta_x' \right) \left(-\frac{\partial \phi_S^S}{\partial y} \right)}_{\text{secondary}} \quad (22b)$$

$$S_{xz} = \underbrace{G \theta_x' \left(\frac{\partial \phi_S^P}{\partial z} + y \right)}_{\text{primary}} + \underbrace{G \left((\theta_x^P)' - \theta_x' \right) \left(-\frac{\partial \phi_S^S}{\partial z} \right)}_{\text{secondary}} \quad (22c)$$

In Eq. 22a, the term $(y^2 + z^2) \cdot (\theta_x')^2/2$ is often described as the “Wagner strain” (Sapountzakis and Tsipiras 2010a).

Local Equilibrium Equation, Primary Torsional Warping Function

In order to establish the local equilibrium equation in the longitudinal direction, the calculus of variations is applied. The principle of virtual work under a total Lagrangian formulation is applied (Eq. 6). Taking into account the primary warping function’s ϕ_S^P virtual components and applying the procedure analyzed in the study of Sapountzakis and Tsipiras (2010a), the following local equilibrium equation:

$$\frac{\partial S_{xx}}{\partial x} + \frac{\partial S_{xy}}{\partial y} + \frac{\partial S_{xz}}{\partial z} - \rho \ddot{u} = 0 \quad \sigma \tau \Omega, \quad \forall x \in (0, L) \quad (23)$$

along with its corresponding boundary condition

$$S_{xy} n_y + S_{xz} n_z = t_x \quad \sigma \tau \Omega \quad \Gamma_j, \quad \forall x \in (0, L) \quad (24)$$

Subsequently, taking into account the secondary warping function’s ϕ_S^S virtual components and applying the same procedure, Eq. 23 can be once again derived. Hence, the two warping functions introduced in the displacement field of the beam should fulfill the local equilibrium Eq. 23 and the corresponding boundary condition Eq. 24. Employing the stress expressions (Eq. 22) and after some algebraic manipulations, it can be easily concluded that the warping functions can be established by the following boundary value problems as

$$\nabla^2 \phi_S^P = 0 \quad \sigma \tau \Omega \quad (25a)$$

$$\frac{\partial \phi_S^P}{\partial n} = (z n_y - y n_z) \quad \sigma \tau \Omega \quad \Gamma_j \quad (25b)$$

$$G \left((\theta_x^P)' - \theta_x' \right) \nabla^2 \phi_S^S - E \left[u'' + (\theta_x^P)''' \phi_S^P + (y^2 + z^2) \theta_x' \theta_x'' \right] + \rho \left[\ddot{u} + (\theta_x^P)' \phi_S^P \right]$$

$$- \left[\left((\theta_x^P)' - \theta_x' \right) (\phi_S^P + \phi_S^S) - \left((\theta_x^P)' - \theta_x' \right) \phi_S^S \right] = 0 \quad \sigma \tau \Omega, \quad \forall x \in [0, L] \quad (26a)$$

$$-G \left((\theta_x^P)' - \theta_x' \right) \frac{\partial \phi_S^S}{\partial n} = t_x \quad \sigma \tau \Omega \quad \Gamma_j, \quad \forall x \in [0, L] \quad (26b)$$

which are considered to be valid at the beam ends as well. In the above equations, $\nabla^2 = \partial^2/\partial y^2 + \partial^2/\partial z^2$ is the Laplace operator, while $\partial/\partial n = (\partial/\partial y)n_y + (\partial/\partial z)n_z$ denotes the derivative with respect to the outward normal vector $\mathbf{n}$ to the boundary

Γ_j (directional derivative). In order to simplify the boundary value problem yielding ϕ_S^S , the usual assumption of ignoring the axial traction component ($t_x \approx 0$) is adopted; hence, relation Eq. 26b is modified as

$$\frac{\partial \phi_S^S}{\partial n} = 0 \quad \sigma_{\tau\theta} \quad \Gamma_j, \quad \forall x \in [0, L] \quad (27)$$

Boundary value problem Eq. 26 can be further simplified, by ignoring the influence of geometrical nonlinearity terms and inertia terms of the secondary warping function and taking advantage of the global equation of motion for the beam which will be formulated in the next section. It can be also proved that ϕ_S^S is a two-dimensional function. Finally, in order to compute unique solutions of Eqs. 25 and 26, ϕ_S^P, ϕ_S^S are considered to fulfill the following orthogonality conditions:

$$\int_{\Omega} \phi_S^P d\Omega = 0 \quad (28a)$$

$$\int_{\Omega} \phi_S^P y d\Omega = 0 \quad (28b)$$

$$\int_{\Omega} \phi_S^P z d\Omega = 0 \quad (28c)$$

$$\int_{\Omega} \phi_S^S d\Omega = 0 \quad (28d)$$

Stress Resultants, Global Equations of Motion

The kinematical unknowns of the problem depend only on the variable x ($u, \theta_x, (\theta_x^P)'$) and will be established from the solution of global differential equations of motion, which will be formulated employing the calculus of variations. In order to facilitate the analysis, the following stress resultants are defined as

$$N = \int_{\Omega} S_{xx} d\Omega \quad (29a)$$

$$M_t^P = \int_{\Omega} \left[S_{xy} \left(\frac{\partial \phi_S^P}{\partial y} - z \right) + S_{xz} \left(\frac{\partial \phi_S^P}{\partial z} + y \right) \right] d\Omega \quad (29b)$$

$$M_t^S = \int_{\Omega} \left(S_{xy} \frac{\partial \phi_S^S}{\partial y} + S_{xz} \frac{\partial \phi_S^S}{\partial z} \right) d\Omega \quad (29c)$$

$$M_w = \int_{\Omega} S_{xx} \phi_S^P d\Omega \quad (29d)$$

where N is the axial force, M_t^P, M_t^S are the primary and secondary twisting moment (Tsipiras and Sapountzakis 2012) resulting from the primary (S_{xy}^P, S_{xz}^P) and secondary (S_{xy}^S, S_{xz}^S) shear stress distribution, respectively, and M_w is the warping moment due to the torsional curvature. Substituting Eqs. 22 into Eq. 29, the stress resultants are obtained as

$$N = EA \left[u' + \frac{1}{2} \frac{I_P}{A} (\theta_x')^2 \right] \quad (30a)$$

$$M_t^P = GI_t^P \theta_x' \quad (30b)$$

$$M_t^S = -GI_t^S \left((\theta_x^P)' - \theta_x' \right) \quad (30c)$$

$$M_w = EC_S (\theta_x^P)'' \quad (30d)$$

where $A = \int_{\Omega} d\Omega$ is the area of the cross section. The geometric constants I_P (polar moment of inertia with respect to the shear center S), I_t^P (primary torsion constant), I_t^S (secondary torsion constant), and C_S (warping constant) are given by the following definitions:

$$I_P = \int_{\Omega} (y^2 + z^2) d\Omega \quad (31a)$$

$$I_t^P = \int_{\Omega} \left(y^2 + z^2 + y \frac{\partial \phi_S^P}{\partial z} - z \frac{\partial \phi_S^P}{\partial y} \right) d\Omega \quad (31b)$$

$$I_t^S = \int_{\Omega} \left[\left(\frac{\partial \phi_S^S}{\partial y} \right)^2 + \left(\frac{\partial \phi_S^S}{\partial z} \right)^2 \right] d\Omega \quad (31c)$$

$$C_S = \int_{\Omega} (\phi_S^P)^2 d\Omega \quad (31d)$$

Applying the principle of virtual work under a total Lagrangian formulation (Eq. 6), taking into account the virtual quantities of $u, \theta_x, (\theta_x^P)'$ (and

their derivatives) and the stress components given by Eq. 22, the Euler–Lagrange equations governing the global dynamic equilibrium of the beam, together with the pertinent boundary conditions at the beam ends $x = 0, L$, are expressed as

$$-\rho A \ddot{u} + \frac{dN}{dx} = -p_x(x, t) \quad (32a)$$

$$\begin{aligned} -\rho I_P \ddot{\theta}_x + \frac{dM_t^P}{dx} + \frac{dM_t^S}{dx} + \frac{d}{dx} \left[\frac{1}{2} EI_n (\theta'_x)^3 + N \frac{I_P}{A} \theta'_x \right] \\ = -m_t(x, t) \end{aligned} \quad (32b)$$

$$-\rho C_S (\ddot{\theta}_x^P)' + \frac{dM_w}{dx} + M_t^S = -m_w(x, t) \quad (32c)$$

$$(N + \bar{N}_0) \delta u(0) = 0 \quad (33a)$$

$$(N - \bar{N}_L) \delta u(L) = 0 \quad (33b)$$

$$\begin{aligned} \left[M_t^P + M_t^S + \frac{1}{2} EI_n (\theta'_x)^3 \right. \\ \left. + N \frac{I_P}{A} \theta'_x + \bar{M}_{t0} \right] \delta \theta_x(0) = 0 \end{aligned} \quad (33c)$$

$$\begin{aligned} \left[M_t^P + M_t^S + \frac{1}{2} EI_n (\theta'_x)^3 \right. \\ \left. + N \frac{I_P}{A} \theta'_x - \bar{M}_{tL} \right] \delta \theta_x(L) = 0 \end{aligned} \quad (33d)$$

$$(M_w + \bar{M}_{w0}) \delta (\theta_x^P)'(0) = 0 \quad (33e)$$

$$(M_w - \bar{M}_{wL}) \delta (\theta_x^P)'(L) = 0 \quad (33f)$$

where $I_n = I_{PP} - I_P^2/A$ and $I_{PP} = \int_{\Omega} (y^2 + z^2)^2 d\Omega$ is the fourth moment of inertia with respect to the shear center S (coinciding with the centroid). In all expressions of Eq. 33, the quantities p_x, m_t, m_w (external axial loading, twisting, and warping moment, respectively) constitute the externally applied time-dependent loading along the beam (Fig. 9a) and arise (through the principle of virtual work) from the externally applied traction vectors t_x, t_y, t_z . The quantities $\bar{N}_0, \bar{N}_L, \bar{M}_{t0}, \bar{M}_{tL}, \bar{M}_{w0}, \bar{M}_{wL}$ (appearing in boundary conditions Eqs. 33a and 33b) constitute externally applied reactions

(axial force, twisting moment, and warping moment, respectively) at the beam end cross sections and are given as

$$\bar{N}_0 = \int_{\Omega_0} t_x d\Omega \quad (34a)$$

$$\bar{N}_L = \int_{\Omega_L} t_x d\Omega \quad (34b)$$

$$\begin{aligned} \bar{M}_{t0} = \int_{\Omega_0} [t_y(-z \cos \theta_x - y \sin \theta_x) \\ + t_z(y \cos \theta_x - z \sin \theta_x)] d\Omega \end{aligned} \quad (34c)$$

$$\begin{aligned} \bar{M}_{tL} = \int_{\Omega_L} [t_y(-z \cos \theta_x - y \sin \theta_x) \\ + t_z(y \cos \theta_x - z \sin \theta_x)] d\Omega \end{aligned} \quad (34d)$$

$$\bar{M}_{w0} = \int_{\Omega_0} t_x \phi_S^P d\Omega \quad (34e)$$

$$\bar{M}_{wL} = \int_{\Omega_L} t_x \phi_S^P d\Omega \quad (34f)$$

From Eqs. 32b, 33c, and 33d, it can be concluded that axial and torsional stress resultants are coupled and cannot be studied independently, which is the case in linear analysis. Introducing the expressions of stress resultants Eq. 30 into Eqs. 32 and 33, the following governing differential equations of motion are obtained as

$$-\rho A \ddot{u} + EA u'' + EI_P \theta'_x \theta''_x = -p_x(x, t) \quad (35a)$$

$$\begin{aligned} -\rho I_P \ddot{\theta}_x + G(I_t^P + I_t^S) \theta''_x - GI_t^S (\theta_x^P)'' \\ + \frac{3}{2} EI_{PP} (\theta'_x)^2 \theta''_x + EI_P u' \theta''_x \\ + EI_P u'' \theta'_x = -m_t(x, t) \end{aligned} \quad (35b)$$

$$\begin{aligned} -\rho C_S (\ddot{\theta}_x^P)' + EC_S (\theta_x^P)''' - GI_t^S ((\theta_x^P)' - \theta'_x) \\ = -m_w(x, t) \end{aligned} \quad (35c)$$

subjected to the initial conditions ($x \in (0, L)$)

$$u(x, 0) = \bar{u}_0(x) \quad (36a)$$

$$\dot{u}(x, 0) = \dot{\bar{u}}_0(x) \quad (36b)$$

$$\theta_x(x, 0) = \bar{\theta}_{x0}(x) \quad (36c)$$

$$\dot{\theta}_x(x, 0) = \dot{\bar{\theta}}_{x0}(x) \quad (36d)$$

$$(\theta_x^P)'(x, 0) = (\bar{\theta}_{x0}^P)'(x) \quad (36e)$$

$$(\dot{\theta}_x^P)'(x, 0) = (\dot{\bar{\theta}}_{x0}^P)'(x) \quad (36f)$$

and to the most general boundary conditions

$$\alpha_1 N + \alpha_2 u = \alpha_3 \quad (37a)$$

$$\beta_1 M_t + \beta_2 \theta_x = \beta_3 \quad (37b)$$

$$\bar{\beta}_1 M_w + \bar{\beta}_2 (\theta_x^P)' = \bar{\beta}_3 \quad (37c)$$

where N , M_w are the axial force and the warping moment at the beam ends given by relations Eqs. 30a and 30d, respectively, while M_t is the twisting moment at the beam ends given as

$$M_t = G(I_t^P + I_t^S)\theta_x' - GI_t^S(\theta_x^P)' + \frac{1}{2}EI_{PP}(\theta_x')^3 + EI_P u' \theta_x' \quad (38)$$

and a_i , β_i , $\bar{\beta}_i$ ($i = 1, 2, 3$) are time-dependent functions specified at the boundary of the beam defining any possible support condition as described in section “Statement of the Problem.” In the above differential equations, viscous damping can be also added without any difficulty. Finally, it is noted that in Eq. 35b, the derivatives of secondary torsion constant with respect to x have been ignored since it can be proved that it is independent of the axial coordinate.

In Eq. 35c, the third derivative of the primary angle of twisting rotation can be observed, thus making the solution of the system more complicated. In order to remove this term, the independent warping parameter $\eta_x = (\theta_x^P)'$ is introduced, and Eqs. 35, 36, 37, and 38 are expressed as

$$-\rho A \ddot{u} + EA u'' + EI_P \theta_x' \theta_x'' = -p_x(x, t) \quad (39a)$$

$$\begin{aligned} & -\rho I_P \ddot{\theta}_x + G(I_t^P + I_t^S)\theta_x'' - GI_t^S \eta_x' \\ & + \frac{3}{2}EI_{PP}(\theta_x')^2 \theta_x'' + EI_P u' \theta_x'' + EI_P u'' \theta_x' \\ & = -m_t(x, t) \end{aligned} \quad (39b)$$

$$-\rho C_S \ddot{\eta}_x + EC_S \eta_x'' - GI_t^S(\eta_x - \theta_x') = -m_w(x, t) \quad (39c)$$

$$u(x, 0) = \bar{u}_0(x) \quad (40a)$$

$$\dot{u}(x, 0) = \dot{\bar{u}}_0(x) \quad (40b)$$

$$\theta_x(x, 0) = \bar{\theta}_{x0}(x) \quad (40c)$$

$$\dot{\theta}_x(x, 0) = \dot{\bar{\theta}}_{x0}(x) \quad (40d)$$

$$\eta_x(x, 0) = \bar{\eta}_{x0}(x) \quad (40e)$$

$$\dot{\eta}_x(x, 0) = \dot{\bar{\eta}}_{x0}(x) \quad (40f)$$

$$\alpha_1 N + \alpha_2 u = \alpha_3 \quad (41a)$$

$$\beta_1 M_t + \beta_2 \theta_x = \beta_3 \quad (41b)$$

$$\bar{\beta}_1 M_w + \bar{\beta}_2 \eta_x = \bar{\beta}_3 \quad (41c)$$

Ignoring all the nonlinear terms of the stress resultants, the initial-boundary value problem of nonuniform torsion problem with STMDE within the range of linear elastic dynamic analysis can be derived. It can be easily concluded that in this simplified problem, the axial and torsional deformation are uncoupled; hence, they can be investigated independently. Moreover, the geometrically nonlinear dynamic problem of nonuniform torsion without STMDE can be described by setting $(\theta_x^P)' = \theta_x'$ in Eq. 21 and following the procedure presented in this section. The differential equations and the boundary conditions of the corresponding simplified initial-boundary value problem are given as

$$-\rho A \ddot{u} + EA u'' + EI_P \theta_x' \theta_x'' = -p_x \quad (42a)$$

$$\begin{aligned} & \rho I_P \ddot{\theta}_x - \rho C_S \ddot{\eta}_x + EC_S \theta_x''' - GI_t^P \theta_x'' \\ & - \frac{3}{2}EI_{PP}(\theta_x')^2 \theta_x'' - EI_P u' \theta_x'' - EI_P u'' \theta_x' = m_t - m_w' \end{aligned} \quad (42b)$$

$$u(x, 0) = \bar{u}_0(x) \quad (43a)$$

$$\dot{u}(x, 0) = \dot{\bar{u}}_0(x) \quad (43b)$$

$$\theta_x(x, 0) = \bar{\theta}_{x0}(x) \quad (43c)$$

$$\dot{\theta}_x(x, 0) = \dot{\bar{\theta}}_{x0}(x) \quad (43d)$$

$$\alpha_1 N + \alpha_2 u = \alpha_3 \quad (44a)$$

$$\beta_1 M_t + \beta_2 \theta_x = \beta_3 \quad (44b)$$

$$\bar{\beta}_1 M_w + \bar{\beta}_2 \theta'_x = \bar{\beta}_3 \quad (44c)$$

where M_t, M_w at the beam ends are given as

$$M_t = \rho C_S \ddot{\theta}'_x + G I_t^P \theta'_x - E C_S \theta'''_x + \frac{1}{2} E I_{PP} (\theta'_x)^3 + E I_P u' \theta'_x - m_w \quad (45a)$$

$$M_w = E C_S \theta''_x \quad (45b)$$

Finally, in order to neglect the influence of nonuniform torsion, it is considered that $C_S = 0$, $m_w = 0$ in Eq. 42b, 45a and in the corresponding simplified initial-boundary value problem, the boundary condition Eq. 44c with respect to warping is neglected.

Secondary Warping Function

The boundary value problem for the evaluation of ϕ_S^S has been defined in section “Local Equilibrium Equation, Primary Torsional Warping Function” (Eqs. 26a and 27). With the aid of the global equilibrium equation of motion Eq. 39c and ignoring the influence of m_w , Eq. 26a is written as

$$\begin{aligned} & (-\rho \ddot{\eta}_x + E \eta''_x) \left(\frac{C_S}{I_t^S} \nabla^2 \phi_S^S - \rho \frac{C_S}{G I_t^S} \ddot{\phi}_S^S - \phi_S^P \right) \\ & - E [u'' + (y^2 + z^2) \theta'_x \theta''_x] \\ & + \rho \left[\ddot{u} - (\ddot{\eta}_x - \ddot{\theta}'_x) (\phi_S^P + \phi_S^S) \right] \\ & = 0 \quad \sigma \tau \Omega, \quad \forall x \in [0, L] \end{aligned} \quad (46)$$

Removing m_w constitutes an assumption similar to $t_x \approx 0$ which has been adopted in section

“Local Equilibrium Equation, Primary Torsional Warping Function.” In order to further simplify the computation of secondary warping function, nonlinear terms $(E u'', E(y^2 + z^2) \theta'_x \theta''_x, \rho \ddot{u})$ as well as inertia terms $(-\ddot{\phi}_S^S \rho C_S / (G I_t^S), \rho (\ddot{\eta}_x - \ddot{\theta}'_x) (\phi_S^P + \phi_S^S))$ appearing in Eq. 26a are neglected. As a consequence, the longitudinal local equilibrium in geometrically nonlinear analysis is partially violated; however, in the corresponding problem in the linear range, local equilibrium is fulfilled, if the inertia terms of the secondary warping function are neglected. Since $\eta_x \neq \theta'_x$ along the beam length, it holds that $(-\rho \ddot{\eta}_x + E \eta''_x) \neq 0$. Consequently, Eq. 46 is written as

$$\nabla^2 \phi_S^S = \frac{I_t^S}{C_S} \phi_S^P \sigma \tau \Omega, \quad \forall x \in [0, L], \quad (47)$$

from which it can be concluded that ϕ_S^S is a two-dimensional time-independent warping function.

Applications

Free Vibrations of Beam of Thin-Walled I-Section Without STMDE

In order to investigate the influence of geometrical nonlinearity on the free vibrations of beams under nonuniform torsion, a beam of an I-shaped cross section ($E = 2.1 \times 10^8 \text{ kN/m}^2$, $G = 8.1 \times 10^7 \text{ kN/m}^2$, $\rho = 8.002 \text{ kNs}^2/\text{m}^4$) of length $L = 4.0 \text{ m}$, having flange and web width $t_f = t_w = 0.01 \text{ m}$ and total height and total width $h = b = 0.20 \text{ m}$, has been studied. Two cases of boundary conditions are studied, while the influence of STMDE is neglected. The ends of the beam are simply supported (according to the torsional boundary conditions), the left end is axially immovable, while the right one is subjected to a constant force $\bar{N}(L, t)$. The initial-boundary value problems described by Eqs. 42, 43, and 44 are solved, in order to obtain the response of the beam in the time domain taking into account or ignoring the influence of axial inertia.

The linear fundamental modeshape of the angle of twist is firstly considered as initial

Nonlinear Dynamic Seismic Analysis,

Fig. 10 Time histories of the angle of twist at the midpoint (a) and axial displacement at the right end point (b) of the beam of application section “Free Vibrations of Beam of Thin-Walled I-Section Without STMDE,” for the case of initial twisting rotations $\bar{\theta}_{x0}(x)$

twisting rotation $\bar{\theta}_{x0}(x)$ along with zero initial twisting velocity $\dot{\bar{\theta}}_{x0}(x)$, while the axial force at the right end is considered to be zero. The normalization of the modeshape is performed by specifying the amplitude of the angle of twist at the midpoint of the beam $\bar{\theta}_{x0}(L/2)$. In Figs. 10 and 11, the time histories of characteristic kinematical components (angle of twist $\theta_x(l/2, t)$ at the midpoint of the beam, axial displacement $u(l, t)$ at the beam's right end), and the twisting moment at the beam's left end $M_t(0, t)$, respectively, are presented for two values of the initial midpoint angle of twist amplitude ($\bar{\theta}_{x0}(l/2) = 1.5$ rad, $\bar{\theta}_{x0}(l/2) = 0.2$ rad) performing two cases of analysis (linear analysis and nonlinear analysis

ignoring axial inertia term). From these figures, the effects of both the nonlinear terms and the initial midpoint angle of twist amplitude are observed on both the kinematical components and stress resultants. It is worth here noting that the pronounced alteration of the twisting moment's time history pattern and a slight change of the amplitude of the angle of twist (which is not clearly shown in Fig. 10a) are attributed to the fact that the fundamental nonlinear modeshape does not coincide with the linear one. Moreover, as it is easily verified from Fig. 10, the frequency of the axial displacement's response is twice as much as the one of the twisting rotation. Moreover, the case of constant along the beam initial

Nonlinear Dynamic Seismic Analysis,

Fig. 11 Time history of the twisting moment at the left end of the beam of application section “Free Vibrations of Beam of Thin-Walled I-Section Without STMDE,” for the case of initial twisting rotations $\bar{\theta}_{x0}(x)$

twisting velocities $\dot{\bar{\theta}}_{x0}(x) = 50$ rad/s, variable along the beam initial axial displacements given from $\bar{u}_0(x) = [\bar{N}(l, 0)/(EA)]x$, along with vanishing initial twisting rotations $\bar{\theta}_{x0}(x) = 0$ and initial axial velocities $\dot{\bar{u}}_0(x) = 0$, applied to the beam with immovable left and free right end subjected to constant axial load $\bar{N}(l, t) = -3,000$ kN according to the axial boundary conditions, has been also studied. In Figs. 12 and 13, the time history of the angle of twist $\theta_x(l/2, t)$ at the midpoint of the beam and $u(l, t)$ at the beam end, respectively, is presented for three cases of analysis, namely, a linear one, a nonlinear complete, and a nonlinear one ignoring the influence of axial inertia. From these figures the influence of geometrical nonlinearity can be once again observed, while the influence of axial inertia proves to be negligible.

Forced Vibrations of Beam of Thin-Walled I-Section Without STMDE

In order to investigate the influence of geometrical nonlinearity on the forced vibrations of beams under nonuniform torsion, the beam of application section “Free Vibrations of Beam of Thin-Walled I-Section Without STMDE” has been

studied ignoring the influence of STMDE. The studied beam is considered to be simply supported (according to the torsional boundary conditions) and subjected to a moving concentrated twisting moment. All of the initial conditions are zero except from the initial axial displacements, which are given from $\bar{u}_0(x) = [\bar{N}(l, 0)/(EA)]x$, while the beam has an immovable left and free right end subjected to constant axial load $\bar{N}(l, t) = -2,500$ kN according to the axial boundary conditions. The concentrated twisting moment has a constant numerical value $M_t = 20.0$ kNm and “travels” with a constant velocity $v = 40$ m/s; thus, the beam is subjected to free vibrations after $t = 0.1$ s. In Fig. 14, the time history of the angle of twist $\theta_x(l/2, t)$ at the midpoint of the beam is presented for the aforementioned cases of analysis (linear, nonlinear) demonstrating the discrepancy of the nonlinear response of the beam compared with that of the linear one in both its forced and free vibrating phase. In Fig. 15, the time history of the axial displacement at the beam’s right end $u(l, t)$ (which is constant in the linear case) is presented for whichever of the aforementioned cases of analysis, the results are not trivial.

Fig. 12 Time history of the angle of twist at the midpoint of the beam of application section “Free Vibrations of Beam of Thin-walled I-Section Without STMDE,” for the case of initial twisting velocities $\dot{\theta}_{x0}(x)$ and initial axial displacements $\bar{u}_0(x)$

Nonlinear Dynamic Seismic Analysis,

Fig. 13 Time histories of the axial stress resultant at the left end (a) and the axial displacement at the right end (b) of the beam of application section “Free Vibrations of Beam of Thin-walled I-Section Without STMDE,” for the case of initial twisting velocities $\dot{\theta}_{x0}(x)$ and initial axial displacements $\bar{u}_0(x)$

Free Vibrations of Beam of Thin-Walled I-Section with STMDE

In order to investigate the influence of STMDE in linear free vibrations of a beam of an open cross section under nonuniform torsion, the beam of application section “Free Vibrations of Beam of

Thin-Walled I-Section Without STMDE” ($I_t^S = 3.048 \times 10^{-4} \text{m}^4$) is examined. The beam’s ends are simply supported according to its torsional boundary conditions, while the left end is immovable and the right end is subjected to a compressive axial load according to its axial

Nonlinear Dynamic Seismic Analysis,

Nonlinear Dynamic Seismic Analysis,

Fig. 15 Time history of the axial displacement at the right end of the beam of application section “[Forced Vibrations of Beam of Thin-Walled I-Section Without STMDE](#)”

boundary conditions. For comparison reasons, the axial load–torsional fundamental natural frequency relation of the aforementioned beam has been investigated. Mohri et al. (2004), without considering the secondary twisting moment deformation effect, proposed analytical load–frequency relations by dropping the

higher-order warping inertia term and assuming that (i) the fundamental modeshape of vibration follows a sinusoidal form $\sin(\pi x/l)$ both in the pre- and post-buckling region, (ii) the beam vibrates harmonically, and (iii) vibrations of small amplitude around a static equilibrium state are performed. These load ($\bar{N}$)–frequency

(ω_f) relations for the pre- and post-buckling regions are given, respectively, as

$$\omega_f^2 = \omega_\theta^2 \left(1 - \frac{\bar{N}}{\bar{N}_{cr,\theta}} \right) \quad (48a)$$

$$\omega_f^2 = 2\omega_\theta^2 \left(\frac{\bar{N}}{\bar{N}_{cr,\theta}} - 1 \right) \quad (48b)$$

where ω_θ is the natural frequency for vanishing axial load and $\bar{N}_{cr,\theta}$ is the torsional buckling load of the beam, respectively, given as (Mohri et al. 2004)

$$\omega_\theta^2 = \frac{\pi^2}{\rho l^2 I_p} \left(\frac{\pi^2 E C_s}{l^2} + G I_t \right) \quad (49a)$$

$$\bar{N}_{cr,\theta} = \frac{A}{I_p} \left(\frac{\pi^2 E C_s}{l^2} + G I_t \right) \quad (49b)$$

According to the results of the presented methodology, the nonlinear initial-boundary value problem (Eqs. 39, 40, and 41) has been solved for several values of constant axial load $\bar{N}$ to obtain the response of the beam in the time domain, taking into account or neglecting the STMDE. The fundamental natural frequency ω_f is then computed by exploiting the first few full cycles of vibration. The computation is based on the fast Fourier transform (FFT) of the time history, while a Hanning data window is employed (Brigham 1988). The free vibrations are initiated by dropping all the torsional loading terms and by employing the linear fundamental modeshape of the angle of twist as initial twisting rotations $\bar{\theta}_{x0}(x)$ along with zero initial twisting velocities $\dot{\bar{\theta}}_{x0}(x)$. In all cases, the STMDE is neglected in the evaluation of $\bar{\theta}_{x0}(x)$. $\bar{\theta}_{x0}(x)$ is computed by employing the methodology presented in the study of Sapountzakis and Tsipiras (2010a) and corresponds to the sinusoidal form assumed by Mohri et al. (2004). In order to perform vibrations of small amplitude, the initial midpoint angle of twist amplitude $\bar{\theta}_{x0}(l/2)$ is chosen closely to the midpoint angle of twist amplitude $\theta_0(l/2)$ corresponding to the static equilibrium state. Mohri et al. (2004) assuming that the twisting deformation mode follows a sinusoidal form

$\sin(\pi x/l)$ proposed the following analytical expression to evaluate $\theta_0(l/2)$

$$\theta_0(l/2) = \begin{cases} 0, & \text{prebuckling region} \\ \pm \sqrt{\frac{8l^2}{3\pi^2 E A I_n} (\bar{N} - \bar{N}_{cr,\theta})}, & \text{postbuckling region} \end{cases} \quad (50)$$

In Fig. 16, the load–frequency relations of Eq. 50 are presented along with pairs of values ($\omega_f, \bar{N}$) obtained from the proposed method, ignoring STMDE. The pairs ($\omega_f, \bar{N}$) are computed by using the values of initial midpoint angle of twist amplitude $\bar{\theta}_{x0}(l/2)$, which are given in Table 7 along with the corresponding values of $\theta_0(l/2)$ computed from Eq. 50. From Fig. 16, the validity of the developed method in predicting $\bar{N} - \omega_f$ pairs of values of beams undergoing small-amplitude torsional vibrations is concluded. The higher discrepancies between the two sets of solutions in the post-buckling region as compared to the ones in the pre-buckling region are attributed to the fact that the previously mentioned assumptions (i), (ii) are valid only in the pre-buckling region. To illustrate this point better, in Fig. 17, the obtained time histories of the angle of twist $\theta_x(l/2, t)$ at the midpoint of the beam for a pre-buckling ($\bar{N} = -1,000$ kN) and a post-buckling ($\bar{N} = -5,000$ kN) axial loading are presented, respectively, demonstrating that only the buckled beam undergoes multifrequency vibrations. For comparison purposes, in Fig. 17b, the time history of $\theta_x(l/2, t)$ employing the nonlinear fundamental modeshape of the angle of twist as initial twisting rotations $\bar{\theta}_{x0}(x)$ (along with zero initial twisting velocities $\dot{\bar{\theta}}_{x0}(x)$) is also included ($\bar{N} = -5,000$ kN), showing that the initiation of free vibrations with the nonlinear modeshape does not induce higher harmonics in the response of the beam. Finally, in Table 8, the obtained results of pairs of values ($\omega_f, \bar{N}$) are presented taking into account or ignoring STMDE and employing either the linear or the nonlinear fundamental modeshape to initiate the free vibrations, showing that in both pre- and post-buckling regions, STMDE does not affect the fundamental natural frequency of beams of open thin-walled cross sections undergoing

Nonlinear Dynamic Seismic Analysis,

small-amplitude vibrations. The insignificance of STMDE for linear static loading conditions of beams of such cross sections has already been reported in the literature (Murín and Kutis 2008).

Primary Resonance of Beam of Thin-Walled I-Section with STMDE

In this application, in order to investigate the influence of geometrical nonlinearity and

STMDE on the response of beams of open cross section under the action of external twisting loading (forced vibrations), the beam of application section “Free Vibrations of Beam of Thin-walled I-Section Without STMDE” is examined under nonuniform torsion in its pre-buckled state. More specifically, the primary resonance of the beam is studied by applying a concentrated twisting moment $M_{t,ext}$ at its midpoint given as $M_{t,ext}(t) = M_{t0} \sin(\omega_{f,lin}t)$, where $M_{t0} = 5$ kNm and $\omega_{f,lin} = 214.23 \text{ s}^{-1}$ (initial conditions $\bar{\theta}_{x0}(x) = 0$, $\bar{\theta}_{x0}(x) = 0$). $\omega_{f,lin}$ is the fundamental natural frequency of the beam undergoing linear torsional vibrations, ignoring STMDE, and is numerically evaluated by performing modal analysis employing Eqs. 39, 40, and 41 and ignoring geometrical nonlinearity. In Figs. 18 and 19, the time histories of the angle of twist $\theta_x(l/2, t)$ at the midpoint of the beam are presented (with or without STMDE) for two cases of analysis, namely, ignoring or considering geometrical nonlinearity, respectively. The linear analyses are carried out by dropping all the nonlinear terms of Eqs. 39, 40, and 41. As expected, only in the linear cases (Fig. 18), deformations continue to increase with time. The beating phenomenon observed in the nonlinear response

Nonlinear Dynamic Seismic Analysis, Fig. 17 Time histories of the angle of twist at the midpoint of the beam of application “Free Vibrations of Beam of Thin-walled

I-Section with STMDE,” for a pre-buckling ($\bar{N} = -1,000$ kN) (a) and a post-buckling ($\bar{N} = -5,000$ kN) axial loading

Nonlinear Dynamic Seismic Analysis, Table 8 Pairs of values $\bar{N}$ (kN), ω_f (s⁻¹) of the beam of application section “Free Vibrations of Beam of Thin-Walled I-Section with STMDE”

(Fig. 19) is explained from the fact that large twisting rotations increase the beam’s fundamental natural frequency ω_f (by increasing the stiffness of the beam), thereby causing a detuning of ω_f with the frequency of the external loading ($\omega_{f,lin}$). After the angle of twist reaches its maximum value, the amplitude of twisting deformations decreases leading to the reversal of the previously mentioned effects.

Nonlinear Dynamic Seismic Analysis,

Fig. 18 Time history of the angle of twist at the midpoint of the beam of application section “Primary Resonance of Beam of Thin-Walled I-Section with STMDE” taking into account or ignoring secondary twisting moment deformation effect – geometrically linear case

Nonlinear Dynamic Seismic Analysis,

Fig. 19 Time history of the angle of twist at the midpoint of the beam of application section “Primary Resonance of Beam of Thin-Walled I-Section with STMDE” taking into account or ignoring secondary twisting moment deformation effect – geometrically nonlinear case

Moreover, in Fig. 20, the time histories of the primary twisting moment M_t^P , the linear secondary twisting moment $M_{t,lin}^S$, the nonlinear twisting moment $M_{t,nl}$, and the total twisting moment $M_t = M_t^P + M_{t,lin}^S + M_{t,nl}$ at the beam's left end are presented taking into account STMDE and performing geometrically nonlinear analysis. It is deduced that the STMDE influences negligibly both kinematical and stress components of beams of open thin-walled cross sections undergoing forced vibrations.

Primary Resonance of Beam of Closed Cross Section with STMDE

In this application, in order to investigate the influence of STMDE on the forced linear vibrations of a beam of closed cross section under nonuniform torsion, a steel beam ($E = 2.1 \times 10^8 \text{ kN/m}^2$, $G = 8.0769 \times 10^7 \text{ kN/m}^2$) of length $L = 5.0 \text{ m}$ and of a hollow rectangular cross section (total height $H = 1.64 \text{ m}$, total width $B = 1.05 \text{ m}$, web thickness $t_w = 0.05 \text{ m}$, and flange thickness $t_f = 0.04 \text{ m}$) is examined.

Nonlinear Dynamic Seismic Analysis,

Fig. 20 Time histories of various twisting moment components at the left end of the beam of application section “Primary Resonance of Beam of Thin-Walled I-Section with STMDE” taking into account the secondary twisting moment deformation effect (geometrically nonlinear analysis)

The geometric constants of the beam are assumed to take the values presented in the study of Murín and Kutiš (2008) ($A = 0.240\text{m}^2$, $I_t = 0.089824\text{m}^4$, $I_t^S = 0.001107\text{m}^4$, $C_S = 0.000193\text{m}^6$). The beam's left end is clamped, and its resonance is studied by applying a distributed twisting moment $m_{t,\text{ext}}$ at $0 < x < 5$ (m) given as $m_{t,\text{ext}}(x, t) = m_{t0} \sin(\omega_{f,\text{lin}} t)$, where $m_{t0} = 5$ kNm/m and $\omega_{f,\text{lin}} = 835, 793\text{s}^{-1}$ ($M_t(l, t) = 0$, vanishing initial conditions $\bar{\theta}_{x0}(x) = 0, \dot{\bar{\theta}}_{x0}(x) = 0$). $\omega_{f,\text{lin}}$ is the fundamental natural frequency of the beam undergoing linear torsional vibrations, ignoring STMDE, and is numerically evaluated by performing modal analysis similarly with applications sections “Free Vibrations of Beam of Thin-Walled I-Section Without STMDE” and “Free Vibrations of Beam of Thin-Walled I-Section with STMDE.”

In Fig. 21, the time histories of the angle of twist $\theta_x(L, t)$, the secondary twisting moment $M_t^S(0, t)$ (scaled quantity $M_t^S(0, t) \times 0, 1$), and the warping moment $M_w(0, t)$, respectively, are presented taking into account or ignoring STMDE. It can be observed that the influence of STMDE on the magnitude of the angle of twist and the torsional stiffness of the beam is negligible, while its influence on the stress resultants is significant and cannot be neglected.

Nonlinear Flexural–Torsional Dynamic Analysis of Beams of Arbitrary Cross Section

Statement of the Problem

Let us consider a prismatic beam of length L (Fig. 22), of constant arbitrary cross section of area A . The homogeneous isotropic and linearly elastic material of the beam's cross section, with modulus of elasticity E , shear modulus G , and Poisson's ratio ν , occupies the two-dimensional multiply connected region Ω of the y, z plane and is bounded by the $\Gamma_j (j = 1, 2, \dots, K)$ boundary curves, which are piecewise smooth, i.e., they may have a finite number of corners. In Fig. 22, CYZ is the principal bending coordinate system through the cross section's centroid C , while y_C, z_C are its coordinates with respect to the Syz shear system of axes through the cross section's shear center S , with axes parallel to those of the CYZ system. The beam is subjected to the combined action of the arbitrarily distributed or concentrated, time-dependent, and conservative axial loading $p_X = p_X(X, t)$ along the X direction, twisting moment $m_x = m_x(x, t)$ along the x direction, and transverse loading $p_y = p_y(x, t)$, $p_z = p_z(x, t)$ acting along the y and z directions, applied at distances y_{p_y}, z_{p_y} and y_{p_z}, z_{p_z} , with respect to the Syz shear system of axes, respectively (Fig. 22b).

Nonlinear Dynamic Seismic Analysis, Fig. 21 Time history of the angle of twist $\theta_x(L, t)$ (a), the secondary twisting moment $M_t^S(0, t)$ (b), the warping moment $M_w(0, t)$ (c) of

the beam of application section “[Primary Resonance of Beam of Closed Cross Section with STMDE](#)”

Under the action of the aforementioned loading, the displacement field of an arbitrary point of the cross section can be derived with respect to those of the shear center as

$$\begin{aligned} \bar{u}(x, y, z, t) = & u(x, t) - (y - y_C)\theta_z(x, t) \\ & + (z - z_C)\theta_y(x, t) \\ & + \theta'_x(x, t)\varphi_S^P(y, z) \end{aligned} \quad (51a)$$

$$\bar{v}(x, y, z, t) = v(x, t) - z \sin(\theta_x(x, t)) - y[1 - \cos(\theta_x(x, t))] \quad (51b)$$

$$\bar{w}(x, y, z, t) = w(x, t) + y \sin(\theta_x(x, t)) - z[1 - \cos(\theta_x(x, t))] \quad (51c)$$

$$\theta_y(x, t) = v'(x, t) \sin(\theta_x(x, t)) - w'(x, t) \cos(\theta_x(x, t)) \quad (51d)$$

$$M_R = \int_{\Omega} S_{xx}(y^2 + z^2) d\Omega \quad (53)$$

which is a higher-order stress resultant. Using the expressions of the stress components (Eq. 52), the stress resultants are obtained as

$$N = EA \left\{ u' + \frac{1}{2} \left(v'^2 + w'^2 + \frac{I_p}{A} \theta_x'^2 \right) - \theta_x' [z_C(v' \cos \theta_x + w' \sin \theta_x) + y_C(v' \sin \theta_x - w' \cos \theta_x)] \right\} \quad (54a)$$

$$M_Y = -EI_Y (w'' \cos \theta_x - v'' \sin \theta_x - \beta_Z \theta_x'^2) \quad (54b)$$

$$M_Z = EI_Z (v'' \cos \theta_x + w'' \sin \theta_x - \beta_Y \theta_x'^2) \quad (54c)$$

$$M_t = GI_t \theta_x' \quad (54d)$$

$$M_w = -EC_S \left(\theta_x'' + \beta_\omega \theta_x'^2 \right) \quad (54e)$$

$$\begin{aligned} M_R = & N \frac{I_p}{A} - 2EI_Z \beta_Y (v'' \cos \theta_x + w'' \sin \theta_x) \\ & - 2EI_Y \beta_Z (w'' \cos \theta_x - v'' \sin \theta_x) \\ & + 2EC_S \beta_\omega \theta_x'' + \frac{1}{2} E \left(I_{pp} - \frac{I_p^2}{A} \right) \theta_x'^2 \end{aligned} \quad (54f, g)$$

where the area A , the principal moments of inertia I_Y, I_Z with respect to the cross section's centroid, the polar moment of inertia I_p , the torsion constant I_t , and the warping constant C_S with respect to the shear center S are given by relations Eqs. 10, 31a, 31b, and 31d, respectively, while $I_{pp} = \int_{\Omega} (y^2 + z^2)^2 d\Omega$ is the fourth moment of inertia with respect to the shear center S defined in section “[Stress Resultants, Global Equations of Motion](#)” as well. Finally, the Wagner's coefficients β_Z, β_Y , and β_ω are given as

$$\beta_Z = \frac{1}{2I_Y} \int_{\Omega} (z - z_C)(y^2 + z^2) d\Omega \quad (55a)$$

$$\beta_Y = \frac{1}{2I_Z} \int_{\Omega} (y - y_C)(y^2 + z^2) d\Omega \quad (55b)$$

$$\beta_\omega = \frac{1}{2C_S} \int_{\Omega} (y^2 + z^2) \phi_S^p d\Omega \quad (55c)$$

Similarly with the previous sections, applying the principle of virtual work (Eq. 6), the equations of motion of the beam can be derived as

$$-N' + \rho A \ddot{u} = p_X \quad (56a)$$

$$\begin{aligned} & [-N(v' - y_C \theta_x' \sin \theta_x - z_C \theta_x' \cos \theta_x)]' \\ & + (M_Z \cos \theta_x)'' + (M_Y \sin \theta_x)'' \end{aligned}$$

$$- \rho A \ddot{v} - \rho A (y_C \sin \theta_x + z_C \cos \theta_x) \ddot{\theta}_x$$

$$+ \rho A (z_C \sin \theta_x - y_C \cos \theta_x) \dot{\theta}_x^2$$

$$- (\rho \{ (I_Y - I_Z) \sin \theta_x \cos \theta_x v' \}$$

$$- [(I_Y - I_Z) \cos^2 \theta_x - I_Y] w' \} \ddot{\theta}_x)'$$

$$- (\rho \{ (I_Y - I_Z) \sin \theta_x \cos \theta_x w' \}$$

$$+ [(I_Y - I_Z) \cos^2 \theta_x - I_Y] v' \} \dot{\theta}_x^2)'$$

$$- [\rho (I_Y - I_Z) \cos \theta_x \sin \theta_x (2\dot{\theta}_x \dot{v}' - \ddot{w}')]'$$

$$+ \left\{ \rho [(I_Y - I_Z) \cos^2 \theta_x - I_Y] (2\dot{\theta}_x \dot{w}' + \ddot{v}') \right\}' = p_Y \quad (56b)$$

$$[-N(w' + y_C \theta_x' \cos \theta_x - z_C \theta_x' \sin \theta_x)]'$$

$$- (M_Y \cos \theta_x)'' + (M_Z \sin \theta_x)''$$

$$+ \rho A \ddot{w} - \rho A (-y_C \cos \theta_x + z_C \sin \theta_x) \ddot{\theta}_x$$

$$- \rho A (z_C \cos \theta_x + y_C \sin \theta_x) \dot{\theta}_x^2$$

$$- (\rho \{ (I_Z - I_Y) \cos \theta_x \sin \theta_x w' \}$$

$$+ [(I_Z - I_Y) \cos^2 \theta_x - I_Z] v' \} \ddot{\theta}_x)'$$

$$+ (\rho \{ (I_Z - I_Y) \cos \theta_x \sin \theta_x v' \}$$

$$- [(I_Z - I_Y) \cos^2 \theta_x - I_Z] w' \} \dot{\theta}_x^2)'$$

where the expressions of the stress resultants are given from Eq. 54. Equation 56 is coupled and highly complicated. This set of equations can be simplified if the approximate expressions (Sapountzakis and Dikaros 2011)

$$\cos \theta_x = 1 - \frac{\theta_x^2}{2!} = 1 - \frac{\theta_x^2}{2} \quad (57a)$$

$$\sin \theta_x = \theta_x - \frac{\theta_x^3}{3!} = \theta_x - \frac{\theta_x^3}{6} \quad (57b)$$

are employed. Thus, using the aforementioned approximations, neglecting the term $\rho A \ddot{u}$ of Eq. 56a denoting the axial inertia of the beam, employing the expressions of the stress resultants (Eq. 54), and ignoring the nonlinear terms of the fourth or greater order (Sapountzakis and Dikaros 2011), the governing partial differential equations of motion for the beam at hand can be written as

$$\begin{aligned}
& -EA \left[u'' + w' w'' + v' v'' + \frac{I_p}{A} \theta'_x \theta''_x - z_C (\theta_x \theta'_x w'' + \theta_x \theta''_x w' + \theta'_x v' + \theta'_x v'' + \theta_x^2 w') \right. \\
& \quad \left. - y_C (\theta_x \theta''_x v' + \theta_x \theta'_x v'' - \theta''_x w' - \theta'_x w'' + \theta_x^2 v') \right] = p_x \quad (58a)
\end{aligned}$$

while the expression of the axial stress resultant N is given as

$$\begin{aligned}
N = EA \left[u' + \frac{1}{2} \left(v'^2 + w'^2 + \frac{I_p}{A} \theta_x'^2 \right) \right. \\
\left. - \theta_x'(z_C(w'\theta_x + v') + y_C(v'\theta_x - w')) \right] \quad (59)
\end{aligned}$$

The above governing differential equations (Eq. 58) are also subjected to the initial conditions ($x \in (0, l)$)

$$u(x, 0) = u_0(x) \quad (60a)$$

$$u_{,t}(x, 0) = u_{0,t}(x) \quad (60b)$$

$$v(x, 0) = v_0(x) \quad (61a)$$

$$v_{,t}(x, 0) = v_{0,t}(x) \quad (61b)$$

$$w(x, 0) = w_0(x) \quad (62a)$$

$$w_{,t}(x, 0) = w_{0,t}(x) \quad (62b)$$

$$\theta_x(x, 0) = \theta_{x0}(x) \quad (63a)$$

$$\theta_{x,t}(x, 0) = \theta_{x0,t}(x) \quad (63b)$$

together with the corresponding boundary conditions of the problem at hand, which are given as

$$a_1 u(x, t) + \alpha_2 N_b(x, t) = \alpha_3 \quad (64)$$

$$\beta_1 v(x, t) + \beta_2 R_{by}(x, t) = \beta_3 \quad (65a)$$

$$\bar{\beta}_1 \theta_Z(x, t) + \bar{\beta}_2 M_{bz}(x, t) = \bar{\beta}_3 \quad (65b)$$

$$\gamma_1 w(x, t) + \gamma_2 R_{bz}(x, t) = \gamma_3 \quad (66a)$$

$$\bar{\gamma}_1 \theta_Y(x, t) + \bar{\gamma}_2 M_{bY}(x, t) = \bar{\gamma}_3 \quad (66b)$$

$$\delta_1 \theta_x(x, t) + \delta_2 M_{bt}(x, t) = \delta_3 \quad (67a)$$

$$\bar{\delta}_1 \theta_{x,x}(x, t) + \bar{\delta}_2 M_{bw}(x, t) = \bar{\delta}_3 \quad (67b)$$

at the beam ends $x = 0, l$, where R_{by} , R_{bz} and M_{bZ} , M_{bY} are the reactions and bending moments with respect to y, z or to Y, Z axes, respectively, given by the following relations (ignoring again the nonlinear terms of the fourth or greater order)

$$\begin{aligned} R_{by} = & N(v' - z_C \theta_x' - y_C \theta_x \theta_x') \\ & + EI_Z(v'''' \theta_x^2 - w'' \theta_x' - w'''' \theta_x - v'''' + 2v'' \theta_x \theta_x' + 2\beta_Y \theta_x' \theta_x'') \\ & + EI_Y(w''' \theta_x + w'''' \theta_x' - 2v'' \theta_x \theta_x' - v''' \theta_x^2 - \beta_Z \theta_x'^3 - 2\beta_Z \theta_x \theta_x' \theta_x'') \end{aligned} \quad (68a)$$

$$\begin{aligned} R_{bz} = & N(w' + y_C \theta_x' - z_C \theta_x' \theta_x) \\ & + EI_Y(w'''' \theta_x^2 + v'''' \theta_x - w'''' + v'' \theta_x' + 2w'' \theta_x \theta_x' + 2\beta_Z \theta_x' \theta_x'') \\ & - EI_Z(v'' \theta_x' + w''' \theta_x^2 + v''' \theta_x + 2w'' \theta_x \theta_x' - 2\beta_Y \theta_x \theta_x' \theta_x' - \beta_Y \theta_x'^3) \end{aligned} \quad (68b)$$

$$\begin{aligned} M_{bZ} = & EI_Z(w'' \theta_x - \beta_Y \theta_x'^2 + v'' - v'' \theta_x^2) \\ & + EI_Y(-w'' \theta_x + v'' \theta_x^2 + \beta_Z \theta_x'^2 \theta_x) \end{aligned} \quad (68c)$$

$$\begin{aligned} M_{bY} = & EI_Z(-w'' \theta_x^2 + \beta_Y \theta_x'^2 \theta_x - v'' \theta_x) \\ & + EI_Y(\beta_Z \theta_x'^2 - w'' + w'' \theta_x^2 + v'' \theta_x) \end{aligned} \quad (68d)$$

while M_t and M_w are the torsional and warping moments at the boundaries of the beam, respectively, given as

$$\begin{aligned} M_{bt} = & GI_t \theta_x' - EC_S \theta_x''' \\ & + N(-z_C w' \theta_x + y_C w' - y_C v' \theta_x - z_C v' + \frac{I_p}{A} \theta_x') \\ & + EI_Z \beta_Y \cdot (-2\theta_x' v'' - 2\theta_x' w'' \theta_x) \\ & + EI_Y \beta_Z (-2\theta_x' w'' + 2\theta_x' v'' \theta_x) + \frac{1}{2} E \left(I_{pp} - \frac{I_p^2}{A} \right) \theta_x'^3 \end{aligned} \quad (69a)$$

$$M_{bw} = -EC_S (\theta_x'' + \beta_\omega \theta_x'^2) \quad (69b)$$

Finally, α_k , β_k , $\bar{\beta}_k$, γ_k , $\bar{\gamma}_k$, δ_k , $\bar{\delta}_k$ ($k = 1, 2, 3$) are time-dependent functions specified at the end cross sections of the beam ($x = 0, l$) as described in section “[Statement of the Problem](#).”

Applications

Forced Vibrations or Beam of Hollow Rectangular Cross Section Under Biaxial Bending

In the first application, in order to demonstrate the strong coupling between flexure and torsion, the beam of application section “[Forced Vibrations or Beam of Hollow Rectangular Cross Section Under Biaxial Bending](#)” ($I_p = 3.16407 \times 10^{-5} \text{m}^4$, $I_{pp} = 3.94264 \times 10^{-7} \text{m}^6$, $I_t = 2.10844 \times 10^{-5} \text{m}^4$, $C_S = 3.59634 \times 10^{-9} \text{m}^6$) is reexamined employing the governing differential equations derived in this section for the most general case (Eqs. 58, 59, 60, 61, 62, 63, 64, 65, 66, and 67). The time histories of $v(l/2, t)$, $w(l/2, t)$ evaluated employing AEM to solve the differential equations of motion (Sapountzakis and Dikaros 2011) occurred identical with the ones presented in Fig. 6 (case without shear deformation). However, what is of interest in this case

Nonlinear Dynamic Seismic Analysis,

Fig. 23 Time history of the angle of twist θ_x at the midpoint of the clamped beam of application section “Forced Vibrations or Beam of Hollow Rectangular Cross Section Under Biaxial Bending”

is the fact that even though the beam is of a doubly symmetric cross section and loaded on its centroid (i.e., no twisting loading is applied), torsional deformation is developed. In Fig. 23, the time history of the angle of twist $\theta_x(l/2, t)$ is presented. As it can be observed, this phenomenon cannot be predicted from linear analysis.

Forced Vibrations or Beam of Monosymmetric Cross Section Under Eccentric Transverse Loading
In this application, in order to investigate the response of a monosymmetric beam and the influence of the loading point upon the cross section, in nonlinear flexural–torsional vibrations, the forced vibrations of a cantilever beam ($E = 2.164 \times 10^8 \text{ kN/m}^2$, $G = 8.0148 \times 10^7 \text{ kN/m}^2$, $\rho = 7.85 \text{ tn/m}^3$, $l = 1 \text{ m}$) of a thin-walled open-shaped cross section (Fig. 24), under two load cases, have been studied (its geometric constants are given in Table 9). More specifically, the beam is subjected to a suddenly applied concentrated force $P_Y(t) = 5 \text{ kN}$ either on the right (load case (i), Fig. 24b) or on the left (load case (ii), Fig. 24c) flange. In Fig. 25, the time histories of the axial displacement $u(l, t)$, the transverse displacements $v(l, t)$, $w(l, t)$, and the angle of twist $\theta_x(l, t)$ of the cantilever beam, respectively, and in Table 10 the maximum values of these kinematical components are presented. From the aforementioned figures and table, it can easily be observed that geometrical nonlinearity affects substantially

the dynamic response of the beam inducing non-vanishing axial displacement and displacement with respect to the z axis, while in linear analysis, these kinematical components vanish. From the obtained results, it can also be verified that the loading position has significant influence on the response, altering substantially the magnitude of the kinematical components. This discrepancy can be explained by the fact that in load case (ii), the change of eccentricity of the transverse load during torsional rotation increases the magnitude of the twisting moment, acting adversely compared with load case (i), where the applied twisting moment is reduced during torsional rotation.

Prismatic Beam of Asymmetric Cross Section Under Harmonic Excitation

In this application, the forced vibrations of a hinged steel L-shaped beam of unequal legs (asymmetric cross section) (Fig. 26a) ($E = 2.1 \times 10^8 \text{ kN/m}^2$, $\rho = 7.85 \text{ tn/m}^3$, $G = 8.0769 \times 10^7 \text{ kN/m}^2$, $l = 1.0 \text{ m}$), having the geometric constants presented in Table 11, are studied. The beam is subjected to a uniformly distributed harmonic loading $p_z(x, t) = p_0(x) \sin(\omega_{f_{lin}} t)$, $p_0(x) = 10 \text{ kN/m}$ as this is shown in Fig. 26. The frequency $\omega_{f_{lin}}$ is considered as $\omega_{f_{lin}} = 2\pi f_{lin}$, where $f_{lin} = 118.2 \text{ Hz}$ is the first natural frequency of the examined beam, performing a linear analysis (Sapountzakis and Dourakopoulos 2009c). Due to lack of

Nonlinear Dynamic Seismic Analysis, Fig. 24 Cantilever beam of application section “**Forced Vibrations or Beam of Monosymmetric Cross**”

Section Under Eccentric Transverse Loading” (a). Transverse force applied on the *right* (b) or on the *left* (c) flange

Nonlinear Dynamic Seismic Analysis, Table 9 Geometric constants of the beam of example 2

$A = 2.66875 \times 10^{-4} \text{ m}^2$	$I_Y = 9.39789 \times 10^{-8} \text{ m}^4$	$I_Z = 4.50061 \times 10^{-7} \text{ m}^4$
$I_p = 9.06833 \times 10^{-7} \text{ m}^4$	$I_t = 9.10243 \times 10^{-9} \text{ m}^4$	$C_s = 1.31047 \times 10^{-10} \text{ m}^6$
$I_{pp} = 4.58807 \times 10^{-9} \text{ m}^6$	$\beta_z = 6.10287 \times 10^{-2} \text{ m}$	$z_c = 3.687 \times 10^{-2} \text{ m}$

symmetry, the beam is expected to develop transverse displacements as well as angle of twist. In Fig. 27, the time histories of the displacements $\tilde{v}(l/2, t)$, $\tilde{w}(l/2, t)$, with respect to the $S\tilde{x}\tilde{y}\tilde{z}$ system of axes and the angle of twist $\theta_x(l/2, t)$, are presented, noting the significant difference in response between linear and nonlinear analyses. More specifically, it is observed that only in the linear response deformations continue to increase with time, while the beating phenomenon observed in the nonlinear one is explained from the fact that large kinematical components increase the beam’s fundamental natural frequency ω_f (by increasing the stiffness of

the beam due to the tensile axial force induced by the axially immovable ends), thereby causing a detuning of ω_f with the frequency of the external loading (ω_{fin}). After the kinematical components reach their maximum values, the amplitude of deformations decreases, leading to the reversal of the previously mentioned effects.

Summary

The main conclusions that can be drawn from this investigation are:

Nonlinear Dynamic Seismic Analysis, Fig. 25 Time history of the axial u (a), transverse v (b), w (c), displacements and angle of twist θ_x (d) at the tip of the cantilever beam of application section “[Forced Vibrations or Beam of Monosymmetric Cross Section Under Eccentric Transverse Loading](#)”

Nonlinear Dynamic Seismic Analysis, Table 10 Maximum values of the kinematical components $u(l, t)$ (m), $v(l, t)$ (m), $w(l, t)$ (m), and $\theta_x(l, t)$ (rad) of the cantilever beam of application section “[Forced Vibrations or Beam of Monosymmetric Cross Section Under Eccentric Transverse Loading](#)” for load cases (i), (ii)

	Linear analysis	Nonlinear analysis	
		Load case (i)	Load case (ii)
$u(l)_{\max}$	0.00000	−0.00085	−0.00119
$v(l)_{\max}$	0.03190	0.03091	0.03217
$w(l)_{\max}$	0.00000	0.00626	0.01230
$\theta_x(l)_{\max}$	−0.38479	−0.32897	−0.50086

- a. In some cases, the effect of shear deformation is significant, especially for low beam slenderness values, increasing both the maximum transverse displacements and the calculated periods of the first cycle of motion.
- b. The discrepancy between the results of the linear and the nonlinear analysis is remarkable.
- c. The geometrical nonlinearity leads to coupling between the torsional and axial equilibrium equations and alters the modeshapes of vibration. Consequently, the initiation of

The coupling effect of the transverse displacements in both directions in the nonlinear analysis influences these displacements.

$I_p = 1.4552\text{E} - 5\text{ m}^4$	$\beta_Z = 3.8866\text{E} - 2\text{ m}$	
$I_{pp} = 1.6873\text{E} - 7\text{ m}^6$	$\beta_\omega = -1.6050\text{E} - 1$	

- small-amplitude free vibrations of buckled beams with the linear fundamental modeshape as initial twisting rotations induces higher harmonics in the beam’s response, but its fundamental natural frequency is only slightly affected.
- d. Large twisting rotations have a profound effect on both the positions around which vibrations are performed and the fundamental natural frequency of buckled beams undergoing large-amplitude free vibrations. The computation of dynamic characteristics of buckled beams differs from the one of beams at a pre-buckled state where the increase of initial amplitude of vibration always leads to an increase of the fundamental natural frequency.
- e. The natural frequency of the axial displacement’s response of buckled beams undergoing large-amplitude free vibrations is twice as much as the one of the twisting rotation, when vibrations are performed around the static equilibrium position of the pre-buckling configuration.
- f. As expected, geometrical nonlinearity bounds the (twisting) deformations of beams at a pre-buckled state subjected to primary resonance excitations. A beating phenomenon is observed in the time histories of kinematical and stress components.
- g. STMDE affects negligibly the kinematical and stress components of beams of open-shaped thin-walled cross sections undergoing free or forced vibrations of small or large amplitude.
- h. STMDE affects the kinematical components of beams of closed-shaped cross sections

**Nonlinear Dynamic
Seismic Analysis,**

Fig. 27 Time history of the displacement $\tilde{v}$ (a), $\tilde{w}$ (b) and of the angle of twist θ_x (c) at the midpoint of the hinged–hinged beam of application section “Prismatic Beam of Asymmetric Cross Section Under Harmonic Excitation”

undergoing linear vibrations. Its effect is much more pronounced on stress components, concluding that it cannot be neglected in linear dynamic analysis of beams of such cross sections.

i. The strong coupling between flexure and torsion may lead beams of doubly symmetric cross sections, undergoing biaxial transverse loading applied on their centroid, to develop torsional rotation.

- j. The eccentricity change of the transverse loading during the torsional beam motion, resulting in additional torsional moment influences the beam response.

Introduction into Basic Concepts of Linear and Nonlinear Behavior

The aim of this contribution is to present the state of the art of nonlinear finite element analysis tools for predicting the collapse load of structures, hence their strength. Reliable evaluation

Nonlinear Finite Element Analysis, Fig. 1 Tension test and linear material behavior

Nonlinear Finite Element Analysis, Fig. 2 Nonlinear material behavior

of collapse load is a powerful tool in structural design in general and in earthquake-resistant design in particular. Collapse may occur due to material nonlinearity, geometric nonlinearity, or a combination of both types of nonlinearity. Some basic concepts of linear and nonlinear structural behavior are therefore briefly reviewed first. For a more in-depth understanding of the associated concepts, the reader should consult pertinent text books (e.g., Bazant and Cedolin 1991).

In classical structural analysis materials are assumed to behave in a linear manner. This behavior is commonly described by a linear stress-strain relation obtained by means of a tension test, as shown in Fig. 1. Stress σ , defined as the applied tensile force P divided by the cross-sectional area A , is then proportional to strain ϵ ,

which is equal to the elongation ΔL of the bar divided by its undeformed length L_0 . This is commonly known as Hooke's law and the proportionality ratio is the modulus of elasticity E of the material:

$$\sigma = E \cdot \epsilon \tag{1}$$

In case the applied load is increased beyond a certain level, the stress-strain relation is no longer proportional. The material behavior then becomes nonlinear, as illustrated in Fig. 2, which provides an out-of-scale description of a tension test for a steel specimen by means of the stress-strain curve, frequently referred also as the material's constitutive law. The green lines denote unloading and may coincide with the corresponding loading curve, in which case the

response is called elastic, or not, and then the response is inelastic. Thus, the behavior is linear in the blue part of the curve in Fig. 2, nonlinear elastic in the orange part, and nonlinear inelastic in the red part. The nonlinear response of common structural materials is characterized by a sharp reduction of stiffness, corresponding to a decrease of the slope of the stress-strain curve.

The ability of a material to deform well into the inelastic range without rupture is called ductility. It is directly related to the material's ability to absorb energy when it is subjected to extreme actions and is a very desirable feature for good seismic behavior. Steel is such a material; thus, a key objective of structural design in seismic regions is to configure layout and detailing of steel and reinforced concrete structures in such a way that material failure rather than other undesirable failure modes is critical, so that proper advantage of its ductility is taken.

In engineering practice, the nonlinear material behavior is commonly described in a simplified manner. Two common such idealizations are the bilinear ones, either elastic-perfectly plastic or elastic-plastic with linear hardening, shown in Fig. 3. The stress corresponding to the end of the linear region is called yield stress of the material and is denoted by f_y , while the maximum stress, also called ultimate stress, is denoted by f_u . The corresponding strains are ϵ_y and ϵ_u , and the difference between them is a measure of the material's ductility. In the elastic-plastic idealization, the higher value of f_u compared to f_y is conservatively ignored.

Thus, by material nonlinearity, we refer to cases where a structure is loaded to such levels that at certain cross sections of certain members, the strains exceed ϵ_y and Hooke's law no longer applies. Material nonlinearity is commonly a critical failure mode for "stocky" structures (Fig. 4), consisting of short members with respect to their cross section and thick sections compared to their overall dimensions.

In order to explain the concept of geometric nonlinearity, it is reminded that in classical structural analysis it is commonly assumed that equilibrium equations can be written in the structure's undeformed configuration. This is theoretically

wrong, as equilibrium of a loaded structure is actually achieved at its deformed configuration. However, in most cases engineering structures possess sufficient stiffness, so that the difference between undeformed and deformed configuration is small and can be safely ignored. As a result, action (usually external loads) and effect (e.g., deformations or internal forces and moments) are proportionally related, as shown in Fig. 5, for a simply supported beam. This type of response is known as geometrically linear. The above assumption simplifies structural analysis significantly and is a prerequisite for the applicability of the principle of superposition, which is at the core of most widely used analysis methods for everyday structures.

Some structures, however, are more flexible, so that the difference between their undeformed and deformed configuration is no longer negligible. One such example is the shallow, two-member truss of Fig. 6, known in the literature as von Mises truss, which exhibits gradual stiffness reduction as applied load increases, eventually leading to a so-called limit point or critical point corresponding to maximum load and zero stiffness.

This type of structural behavior is called geometrically nonlinear and invalidates the use of the principle of superposition, thus of all commonly used structural analysis methods. The so-called nonlinear analysis methods are required, often involving iterations to achieve convergence, as equilibrium equations must now be formulated in the deformed geometry, which however is unknown. Thus, nonlinear analysis is a lot more time and computationally demanding than linear ones. Typical examples of structures that are prone to geometric nonlinearity are cables subjected to transverse loads, shallow arches and domes, slender bars that buckle under axial compression, and thin-walled shells (Fig. 7).

It is noted here that almost all structures behave linearly for low load levels and nonlinearly above a certain load level. Moreover, collapse of most structures is associated with combined material and geometric nonlinearity. As noted above, stocky structures (structures of small slenderness) are more susceptible to

Nonlinear Finite Element Analysis, Fig. 3 Common idealizations of nonlinear material behavior

Elastic-perfectly plastic behavior

Elastic-plastic behavior with linear hardening

material nonlinearity; therefore, collapse initiation is governed by material nonlinearity. Then, as collapse progresses, stiffness decreases very rapidly, large deformations and strains occur, and therefore geometric nonlinearity develops as well, as illustrated in Fig. 8, where linear behavior is denoted with blue color, material nonlinearity with orange, and combined material and geometric nonlinearity with red.

Slender structures on the other hand are flexible and exhibit large deformations; thus, they are more susceptible to geometric nonlinearity;

therefore, collapse initiation is due to geometric nonlinearity. As collapse progresses, stiffness decreases further very rapidly, even larger deformations and strains occur, and therefore material nonlinearity develops as well. This type of behavior is described in Fig. 9, where linear behavior is denoted with blue color, geometric nonlinearity with green, and combined material and geometric nonlinearity with red.

Moreover, as structures enter into their nonlinear range, their behavior is affected by the unavoidable presence of initial imperfections,

Nonlinear Finite Element Analysis, Fig. 4 Stocky structure that is prone to material nonlinearity

including geometric irregularities, material and cross section inhomogeneities, load eccentricities, etc. This is illustrated in Fig. 10 for the example of a shallow arch subjected to a vertical concentrated load at its crown, where the presence of imperfections drastically reduces the arch's strength, depending also on their magnitude w_0 .

It is thus concluded that the capacity of a structure depends on its sensitivity to material nonlinearity, geometric nonlinearity, and initial imperfections. Therefore, all these factors should be taken into account in order to predict the structure's collapse, thus evaluate its strength.

Treatment of Nonlinear Behavior in Engineering Practice

In recent years structural design codes have adopted limit state design (LSD), replacing the older concept of allowable stress design (ASD). Limit state design requires the structure to satisfy two principal criteria: the ultimate limit state (ULS) and the serviceability limit state (SLS). A limit state is a set of performance criteria that must be met when the structure is subject to loads. To satisfy the ultimate limit state, the structure must not collapse when subjected to any of the pertinent combinations of its design loads. To satisfy the serviceability limit state criteria, a structure must remain functional for its intended use subject to routine, everyday loading.

Nonlinear Finite Element Analysis, Fig. 5 Linear response of a simply supported beam

The prevailing approach proposed in modern codes for carrying out ultimate limit state checks consists of obtaining action effects by means of linear elastic analysis of the structure subjected to design loads and comparing them to resistances that account for both types of eventual nonlinearity, material, and geometric. Thus, prediction of collapse, a highly nonlinear phenomenon, is accomplished by means of linear elastic analysis.

In order to evaluate strength, modern codes assume full exploitation of material capacity and appropriate reduction factors, by means of which geometric nonlinearities and imperfections are taken into account. For example, the strength of a steel bar subjected to compression is given by Eurocode 3 (European Committee for Standardisation 2004) as:

$$N_{b,Rd} = \frac{\chi \cdot \beta \cdot A \cdot f_y}{\gamma_{M1}} \quad (2)$$

In this relation, A is the cross-sectional area and f_y the material's yield strength; thus, the product $A \cdot f_y$ represents the cross section's axial strength and addresses the issue of material nonlinearity, adopting an elastic-perfectly plastic idealization of the constitutive law. On the other hand, χ is a reduction factor accounting for global buckling, obtained from the so-called buckling curves, which have been calibrated for

Nonlinear Finite Element Analysis, Fig. 6 Shallow two-bar truss and its geometrically nonlinear response

Nonlinear Finite Element Analysis, Fig. 7 Slender structures that are prone to geometric nonlinearity

specific types of cross sections by means of a wide range of experimental results, and incorporates the effects of initial imperfections and residual stresses, while β is a reduction factor accounting for local buckling, depending on the classification of the cross section into appropriate slenderness categories. Thus, the product $\chi \cdot \beta$ addresses the issues of geometric nonlinearity and imperfections.

The above approach offers significant advantages, as it is straightforward and the prediction of collapse is accomplished by means of linear elastic analysis. This means that it can be carried out using widely available commercial software, is computationally inexpensive, and does not require special expertise of the engineer in setting up the structural model, selecting the analysis parameters, and interpreting the results.

Nonlinear Finite Element Analysis, Fig. 8 Typical load-displacement curve of stocky structures

Nonlinear Finite Element Analysis, Fig. 9 Typical load-displacement curve of slender structures

Nonlinear Finite Element Analysis,

Fig. 10 Influence of imperfections on strength of shallow arch

Furthermore, the results are quite reliable for ordinary structural systems.

Although this approach is appropriate for the design of ordinary structural systems, more complex structures with unusual geometry or cross sections require more accurate methods of their strength evaluation, as such cases are not directly covered by buckling curves and interaction equations between different action components, while simplifying assumptions that are made in an effort to approximate their behavior may lead to significant inaccuracies. To address such cases, modern structural design codes allow predicting collapse by means of more elaborate, nonlinear numerical analysis, taking also initial imperfections into account.

Prediction of collapse of structures can thus be accomplished by means of such nonlinear numerical analysis, making use of commercially available finite element software, setting up an appropriate finite element model, obtaining critical buckling modes from Linearized Buckling Analysis (LBA), and then using a linear combination of these modes as imperfection pattern for a Geometrically and Material Nonlinear

Imperfection Analysis (GMNIA). Equilibrium paths accompanied by snapshots of deformation and stress distribution at characteristic points are then used for evaluating the results of the GMNIA analysis. This approach is particularly applicable to seismic design, as all major seismic design codes allow structures to behave inelastically during major earthquakes, defining “no collapse” as the design objective.

In the following, practical details of the implementation of this approach are discussed, and pertinent case studies are presented. It is thus aimed to contribute towards making advanced numerical analysis methods accessible to practicing structural engineers, by providing guidelines for using such methods for structural design and by demonstrating some of the capabilities afforded by such methods to the structural engineering community.

Overview of Linearized Buckling and Nonlinear Numerical Algorithms

The geometric and material nonlinear phenomena characterizing structures near collapse are very complicated in nature and require, in most cases, highly sophisticated numerical tools for their simulation. A common feature of most nonlinear analysis algorithms is that the load is applied in successive steps and iterations are performed within each step to achieve convergence (Stricklin et al. 1973).

The simplest numerical method for a detailed geometrically and material nonlinear (GMN) analysis is the Newton-Raphson scheme (Crisfield 1979; Bathe 1995), which can be found in three forms: (i) the full Newton-Raphson, which is the most accurate, but also the most time consuming, since the tangent stiffness of the structure has to be calculated and factorized within each iteration in the solution procedure; (ii) the modified Newton-Raphson, which differs from the full Newton-Raphson in that the calculation and the factorization of the tangent stiffness matrix take place only in some iterations within each step, thus requiring in most cases a larger number of iterations per step but

a smaller computational effort per iteration; and (iii) the “initial stress” Newton-Raphson procedure, where the calculation of the tangent stiffness matrix is performed once, at the beginning of the analysis, and then kept the same throughout the analysis (Fig. 11).

Applying the Newton-Raphson method in a nonlinear finite element system will yield results only in the pre-collapse range, but it will fail to give information about the post-collapse response. To circumvent this limitation, a constraint can be added into the finite element system, which relates the load increment and the incremental displacements within each iteration (Fig. 12). This technique allows the calculation of the whole equilibrium path, even beyond the critical limit points. A number of different solution algorithms have been proposed in the literature (Riks 1979; Crisfield 1981; Ramm 1981; Bathe and Dvorkin 1983).

In case initial imperfections are also included in the numerical model, the above GMN analysis is denoted as GMNIA. Such analyses are often preceded by linearized buckling analyses (LBA) (Bathe 1995), which seeks deformed configurations of the structure that correspond to zero determinant of a characteristic stiffness matrix, assuming linear response beyond an initial configuration. Such deformed configurations are known as buckling modes and the corresponding loads as linear critical buckling loads. Critical buckling loads obtained by means of LBA are, in most cases, not safe predictions of strength. However, it is advisable that this type of analysis precedes the subsequent, more exact, nonlinear analyses, for several reasons (Dimopoulos and Gantes 2012):

- (i) Critical buckling loads obtained by means of linearized buckling analyses are an initial indication, and in most cases an upper bound, of actual strength. Taking also into account the fact that this is a very fast and inexpensive type of analysis, it may be very useful as a tool for evaluating alternative solutions during preliminary design, before resorting to the much more time-consuming and expensive nonlinear analyses.

Nonlinear Finite Element Analysis, Fig. 11 Variations of the Newton-Raphson method

- (ii) Critical buckling loads are often needed for calculating nondimensional slenderness ratios to be used with buckling curves in the framework of code-based design procedures. Even though analytical expressions for these buckling loads are available for simple cases of geometry, loading patterns, and boundary conditions, in the majority of other cases, buckling loads must be obtained numerically.
- (iii) It has been shown that buckling analysis can be used in place of a geometrically

- nonlinear analysis for the calculation of the nonlinear stability limit of a number of structures by performing a number of successive buckling analyses on the unstressed and some stressed configurations of the structures (Chang and Chen 1986; Dimopoulos and Gantes 2012).
- (iv) Buckling modes obtained by means of linearized buckling analyses are commonly used as initial imperfections for geometrically and material nonlinear imperfection analyses. Such imperfections are necessary

in order to trigger all possible failure mechanisms and to make sure that the critical failure mechanism is captured by the nonlinear numerical analysis algorithm.

It should be noted that the choice of buckling modes as imperfection patterns is not unique and has in many cases been found to lead to lower compliance to experimental results than other shapes of initial imperfections. For the case of cylindrical shell structures, a type of structures that is particularly sensitive to imperfections, imperfections affine to the collapse mode of the perfect shell were found to be more unfavorable than ideal buckling modes (Schneider and Brede 2005; Schneider et al. 2005). Furthermore, fabrication processes are responsible for imperfection patterns, creating residual stress profiles in the body of the cross sections, which can have significant consequences on the ultimate bearing capacity of steel structures (Berry et al. 2000; Herynk et al. 2007). However, the choice of manufacturing-related imperfection patterns is usually dependent upon the structural type as well as the specific manufacturing method, cannot be easily generalized, and often lacks adequate data to be properly implemented. In case such information is available, it is, in general, preferable to use these imperfection patterns, as they more accurately represent real strength.

In the absence of such data, however, the use of buckling modes as imperfection shapes is considered to be the next best available choice.

Details of the formulation and implementation of these algorithms are beyond the scope of this presentation, and the reader should consult other specialized texts for that purpose. The engineers applying this methodology should have good knowledge of theoretical and practical aspects of the finite element method for linear and nonlinear structural applications (as outlined, e.g., by Crisfield et al. 1997; Bathe and Cimento 1980; Bathe et al. 1980; Bathe 1995; Belytschko et al. 2000; Kojic and Bathe 2004). Emphasis here is placed on the application of such methods to determine structural collapse, thus strength. For that purpose, the successive steps of a proposed numerical methodology are presented, followed by two case studies, referring to steel members with unconventional geometry that are part of two long-span roofs, which have been recently designed in Greece.

Numerical Methodology for Collapse Prediction

A state-of-the-art strategy for understanding the behavior, predicting all possible failure mechanisms, evaluating the strength, and assessing the vulnerability of structures based on advanced nonlinear numerical analyses consists of the following steps (Gantes and Fragkopoulos 2010; Gantes 2011; Gantes and Koulatsou 2013):

Step 1. Setting up an appropriate finite element model

In this step special attention should be paid to the following:

- (i) The finite element software, the specific elements used to model the structure, as well as the numerical solution algorithm employed for numerical analysis should be verified, by means of comparisons to analytical solutions and/or numerical solutions from the literature.
- (ii) The model should be able to predict all anticipated failure mechanisms.

Nonlinear Finite Element Analysis,

Fig. 13 Architectural proposal for the steel roof over Aristotle's Lyceum

Nonlinear Finite Element Analysis,

Fig. 14 Perspective view of the suspended steel roof over Aristotle's Lyceum

For example, modeling a steel column with beam elements is not appropriate for predicting failure where local or lateral buckling may be predominant. Shell or plate elements should be used instead, and the mesh should be fine enough to capture the curvature part of the cross section where local or lateral buckling occurs.

- (iii) Basic features of the model, such as element connectivity, boundary conditions, and loads, should be checked by means of simple, linear, static, and modal analyses. Sum of support reactions can be used to check load application. Mode

shapes and periods of vibration can be compared to expected values, in order to identify possible errors in mass or stiffness.

- (iv) The mesh density should be verified by performing a convergence study. Element size should be successively divided in half, and representative quantities of the response should be plotted against mesh density until sufficient convergence is achieved. It should be noted that a finer mesh may be required for subsequent nonlinear analyses than the one obtained from linear static

Nonlinear Finite Element Analysis, Fig. 15 View of a suspended main arch and the corresponding pylon of the steel roof over Aristotle's Lyceum

Nonlinear Finite Element Analysis, Fig. 16 Cross sections of pylon

convergence study. However, the latter one should be considered as a minimum.

Step 2. Carrying out linearized buckling analysis

One question arising when carrying out such an analysis concerns the number of modes that should be evaluated. Even though the first buckling mode is the one corresponding to the lowest critical buckling load, it is, in general, not sufficient, for several reasons. A higher mode associated with an unstable post-buckling equilibrium path may be more critical than a lower one with a stable post-buckling equilibrium path, due to its sensitivity to imperfections. Even two modes with stable post-buckling equilibrium paths, but with nearly coinciding critical buckling loads, may interact in the presence of imperfections and lead to unstable post-buckling behavior (e.g., Bazant and Cedolin 1991; Livanou et al. 2013). Therefore, several buckling modes should be obtained. There is no clear-cut criterion as to their number; however, it is recommended to obtain sufficient number of modes, so that the critical buckling load of the last mode is sufficiently larger than that of the first mode, in order to eliminate any possibility of mode interactions and the

associated detrimental effects for the bearing capacity of the structure.

Step 3. Carrying out nonlinear analysis with imperfections

Taking all above discussion into account, a geometrically and material nonlinear imperfection analysis (GMNIA) is recommended for reliably understanding the behavior, predicting all possible failure mechanisms, evaluating the strength, and assessing the vulnerability of structures. In many cases it is useful to carry out first separate analyses accounting only for material nonlinearity (MNIA) and geometric nonlinearity (GNIA), which help identify the prevailing failure mechanism of the structure in question. But the ultimate strength evaluation should always be based on GMNI analyses, accounting for both types of nonlinearity. Several decisions, related to the details of this type of analysis, arise and must be considered by the engineer:

- (i) *Shape of initial imperfections:* As stated above, in the absence of experimental data on manufacturing-related imperfection patterns, it is widely recognized as appropriate to use a linear combination of the critical buckling modes obtained from

Nonlinear Finite Element Analysis, Fig. 21 Detail of von Mises stress distribution at characteristic point C along the GMNIA equilibrium path of pylon of steel roof over Aristotle’s Lyceum (kN/m²)

Nonlinear Finite Element Analysis, Fig. 22 Finite element model of two adjacent main arches of steel roof over Aristotle's Lyceum

linearized buckling analysis as the shape of initial imperfections. Regarding the number of critical buckling modes, reference is made to the discussion in step 2 above. In the absence of any available information about the relative importance of individual modes, equal weights may be assumed for their linear combination.

- (ii) *Amplitude of initial imperfections:* With the exception of cases with steep unstable post-buckling equilibrium paths, for example, frequently encountered for thin-walled shells, the size of initial imperfections is not very important for the type of response and the values of critical response quantities obtained from the analysis. For certain types of structures, pertinent codes specify recommended magnitudes of imperfections or manufacturing and erection tolerances that can be regarded as upper bounds of imperfection magnitudes (European Committee for Standardisation 2004). In some cases, a parametric study for different sizes

within the range of realistic construction tolerances may provide valuable insight into the effect of imperfection magnitude on ultimate strength.

- (iii) *Details of numerical algorithm:* As mentioned above, all numerical algorithms for nonlinear structural analysis rely on applying the loads in small steps, performing iterations of linear analyses within each step until a predefined convergence criterion is met, and using the final configuration of the structure at each step as a starting configuration for the next one. The choice of an arc-length algorithm with either MNR (as a first alternative) or NR (in cases of convergence difficulties) iterations is recommended for GMNI analyses for practical applications. If convergence difficulties are still encountered, the engineer may have to increase the default number of maximum iterations per step or relax the convergence tolerances, but in the second case, special attention is recommended, as erroneous

Nonlinear Finite Element Analysis, Fig. 23 Cross sections of main arch

Nonlinear Finite Element Analysis, Fig. 24 First buckling mode of two adjacent main arches of steel roof over Aristotle's Lyceum

Nonlinear Finite Element Analysis,

Fig. 25 Equilibrium paths of two adjacent main arches of steel roof over Aristotle's Lyceum

convergence to configurations without physical meaning may be obtained.

- (iv) *Evaluation of results:* It is recommended to evaluate the results of GMNI analyses by using a plot of the equilibrium path, accompanied by characteristic snapshots of the structure's deformation and stress distribution along this path. The equilibrium path is a plot of a characteristic response quantity (usually on the horizontal axis) with respect to the external action (usually on the vertical axis). Very often the external action is represented by a load multiplier, λ , which acts upon the required design loads. Particular attention is needed for the selection of the characteristic response quantity of the horizontal axis, which should be representative of the overall structural response and not of some local phenomena, depending also on the critical failure mode. Multiple equilibrium paths for more than one response quantity may be useful in some cases.

Snapshots of the structure's deformation and stress distribution at characteristic points (e.g., before and after change of slope or change of curvature, at the ultimate limit point, at the end of the curve) are very useful in appreciating the physical phenomena occurring with progressing external loading.

Important quantities of an equilibrium path include: (a) the slope of its initial, usually straight, part, representing the structure's initial stiffness; (b) the maximum value of the external action, representing the structure's strength; (c) the amplitude of displacements corresponding to the maximum value of the external action, pointing out whether serviceability problems may be encountered before failure; and (d) the maximum deformation at failure, as well as the area between the equilibrium path and the horizontal axis, particularly in the post-linear range, representing the structure's ductility.

Comparison of representative numerical results with experimental measurements, if available, is strongly encouraged as a means for calibrating and verifying the numerical results. Numerical analysis can then, with increased reliability, be extended for other cases of geometry, cross sections, material, boundary conditions, or loads, thus performing "numerical experiments" that may help optimize the design.

Case Studies

The abovementioned approach, making use of advanced nonlinear numerical analyses, is

Ministry of Culture, and the preliminary architectural proposal (Fig. 13) of the present suspended steel roof was awarded the first prize.

The roof steel structure (Fig. 14) consists of six parallel main arches having a span of 60 m and spaced at a distance of 10.5 m that are interconnected by means of purlins and horizontal bracings. Each main arch is pinned on the ground on one edge, while the other edge is supported by a V-shaped column. The arches are suspended by prestressed cables from a 25 m tall pylon, which has a slight inclination with respect to the vertical plane. The stability in and out of plane of the pylons is ensured by two back-stayed prestressed cables.

On the exterior of the pylons and V-shaped columns, independent steel structures for the

extension of the cladding as well as eccentric vertical bracings for contributing to the resistance against lateral loads transversely to the main arches are provided.

The main arches (Fig. 15) consist of bending and compression members, which are made of built-up cross sections, varying along the length, having the shape of a rectangular box (green, cyan, and red parts in Fig. 15) and an I shape in the remaining parts (blue parts in Fig. 15). The 25 m tall pylons (Fig. 15) are compression members with hollow circular cross section, varying over the height in both diameter and wall thickness. For the design of these two members, main arches and pylons, numerical models have been created and analyzed linearly and nonlinearly.

Nonlinear Finite Element Analysis, Fig. 37 First buckling mode (lateral buckling) of two secondary beams and their cross-bracing in the steel roof of Panathinaikos stadium

Nonlinear Finite Element Analysis, Fig. 38 Second buckling mode (local buckling) of two secondary beams and their cross-bracing in the steel roof of Panathinaikos stadium

With respect to the resistance of the pylon in compression, the applicability of buckling curves and associated reduction factors is questionable due to the varying cross section (Fig. 16). In order

to obtain the pylon's strength against compression, a shell finite element model has been created, shown in Fig. 17. A conceptual design decision was taken, to use cross sections of class

Nonlinear Finite Element Analysis,

Fig. 39 Equilibrium paths of secondary beams of Panathinaikos stadium

1 or 2 for the pylon, to avoid local buckling as a possible failure mechanism. This was confirmed by the linearized buckling analysis, which showed no local buckling modes among the first ten, and thus, only the shape of the first global flexural buckling mode, presented in Fig. 18, was used as initial imperfection for nonlinear analyses.

Then, GNI and GMNI analyses were carried out for this imperfection shape having the magnitude prescribed by Eurocode 3 specifications, and the corresponding equilibrium paths are shown in Fig. 19. It is observed that the presence of imperfections reduces significantly the elastic critical load with respect to the linear one, as expected. Failure is encountered on the ascending branch of the equilibrium path, and it is mainly due to material yielding, accompanied by moderate global flexural buckling. This is verified by the deformation and stress snapshots on three characteristic points A, B, and C, before, on, and beyond the critical point, shown in Figs. 20 and 21. The clear formation of plastic hinges at two locations, highlighted in Fig. 21, helps identify these cross sections as weak. These locations are characterized by a decrease of cross-sectional thickness, so that increased thickness at these areas would be the most appropriate way for improving overall pylon strength.

With respect to calculation of the ultimate strength of the main arch, the use of code provisions is also of questionable validity due to its unusual shape and cross sections, thus rendering evaluation of the resistance to lateral buckling with analytical tools unreliable. For that purpose, a finite element model of two arches with their interconnecting purlins and bracings has been created, illustrated in Fig. 22. Similarly to the pylon, cross sections (Fig. 23) of class 1 or 2 were used for the main arches, so that local buckling was not critical. This model is able to simulate the behavior of the system regarding lateral buckling in a reliable manner, since bracings provide realistic lateral support to the system. Main arches and purlins are modeled with shell elements, whereas horizontal bracings are modeled with beam elements and cables with nonlinear, tension-only prestressed truss elements.

First, linearized buckling analysis was performed in order to obtain the first critical buckling mode (Fig. 24), which was used as shape of initial imperfection for the subsequent nonlinear analyses. GNI and GMNI analyses were then carried out, and their equilibrium paths are displayed in Fig. 25, accompanied by corresponding snapshots of deformed geometry and stresses for characteristic points A, B, C, and D along the GMNIA paths, illustrated in Figs. 26

and 27, respectively. The reference loads applied for the nonlinear analyses were chosen equal to the design loads corresponding to the most onerous load combinations. The multiplying load factor reported on the vertical axis of the equilibrium path (Fig. 25) denotes the percentage of reference

loads acting on the structure at each load step. As observed, the maximum load factor for the main arches is approximately equal to 1.1, which represents a rather low factor of safety against collapse and signifies a possible need for strengthening.

Nonlinear Finite Element Analysis, Fig. 40 (continued)

Point C

Nonlinear Finite Element Analysis, Fig. 40 Deformation at characteristic points along the GMNIA equilibrium path of the secondary beams of Panathinaikos stadium

From the above discussion and the deformed shapes and stress contours of Figs. 26 and 27, it is concluded that the box-shaped cross sections at the lower end, combined with the lateral support provided by the bracing system, are sufficient for preventing lateral buckling; thus, failure is primarily due to material yielding, with the formation of plastic hinges becoming particularly evident from the deformation and stress pictures on the descending branch of the equilibrium path. This is also verified by the stress contours detail shown in Fig. 28, corresponding to the equilibrium path of GMNI analysis point D. From the deformed shape of main arches (Fig. 29), it is also observed that the system has little lateral deformation, while vertical deflections dominate.

Figures 28 and 29 are also very useful in identifying as weak the locations of cross section change from double box section to I section (sections 3'-3' and 4'-4' in Fig. 23). An extension of the box section or a more gradual transition to the I section would thus be an appropriate intervention for improving the collapse behavior of the arch and enhancing its ultimate strength.

Moreover, it is verified for this example also that the elastic critical load derived from linearized buckling analysis is reduced significantly due to geometric imperfections and material yielding.

Roof of Panathinaikos Football Stadium

The second case study refers to the secondary beams of the steel roof in the new football stadium of Panathinaikos FC, which will be constructed in Votanikos, Athens, Greece, with a maximum capacity of approximately 40,000 spectators. A perspective view of the structural parts of the stadium is shown in Fig. 30 and its plan view in Fig. 31.

The roof has the shape of a cylindrical surface, and it consists of four structurally independent parts. The basic element of each part is a main truss girder, simply supported on reinforced concrete pylons, arranged at the four corners of the stadium, as shown also in the sections of Fig. 32. Secondary beams are supported on these main girders and on the exterior peripheral reinforced concrete columns of the grandstands (Figs. 33

and 34). These beams carry the roof cladding. Appropriately arranged cross-bracings contribute to the overall stability.

Aim of the numerical investigation presented here is the evaluation of the ultimate capacity of secondary beams. These beams have different

lengths, depending on their location, so that they adjust to the overall roof geometry. In the initial structural design, which is described here, they were made of welded I-shaped cross sections with variable height over their length, as illustrated in Fig. 35. The unusual geometry and cross

Point C

Nonlinear Finite Element Analysis, Fig. 41 Von Mises stresses at characteristic points along the GMNIA equilibrium path of secondary beams of Panathinaikos stadium (kN/m^2)

Nonlinear Finite Element Analysis, Fig. 42 Detail of von Mises stresses distribution of characteristic point C along the GMNIA equilibrium path of two adjacent secondary beams of Panathinaikos stadium (kN/m^2)

Nonlinear Finite Element Analysis, Fig. 43 Final cross sections of secondary beams of Panathinaikos stadium

sections of the beams highlighted the need for advanced numerical modeling and analyses, in order to address in a reliable manner the lateral and local buckling issues that were encountered.

In order to evaluate the behavior of secondary beams against lateral and local buckling and their strength, a finite element model consisting of two adjacent secondary beams and their cross-bracing members was created, shown in Fig. 36. Secondary beams were modeled with shell elements and cross-bracing members with beam elements. Secondary beam support on the main truss girders was modeled with spring elements.

First, linearized buckling analysis was performed in order to estimate the buckling modes and corresponding critical loads for both lateral and local buckling. The first two buckling modes are presented in Figs. 37 and 38, which illustrate the first lateral buckling mode and the first local buckling mode, respectively. A linear combination of these two first buckling modes was used as initial imperfection for the GMNI analysis.

GNI and GMNI analysis were performed, and the results are displayed by means of the equilibrium paths, shown in Fig. 39, and the snapshots of deformation and stress distribution for characteristic points A, B, and C along the GMNIA equilibrium path (Figs. 40 and 41). As in the previous example, the multiplying load factor reported on the vertical axis of the equilibrium path (Fig. 39) denotes the percentage of reference loads acting on the structure at each load step. In this case the maximum load factor for the main arches is approximately equal to

1.5, however, a significant reduction of stiffness is observed for much lower loads.

It is observed that failure was due to combined lateral buckling and material yielding, with small contribution from local buckling, as indicated by the equilibrium path and the corresponding deformation and stress distribution (Fig. 42). As in the first case study, here also the elastic critical buckling load derived by linearized buckling analysis decreases due to geometric imperfections and material yielding.

Due to the stiffness reduction occurring at low load levels, as mentioned above, associated with onset of lateral buckling, it was decided to change the beams' cross section from I-shaped to narrow box cross sections with protruding flanges that vary over their length (Fig. 43), in order to improve their torsional inertia, thus increasing their stiffness against lateral buckling.

Summary

For structures with unusual shape and variable cross sections, for which the use of pertinent codes and recommendations requires simplifying assumptions of questionable validity, an alternative approach has been presented for understanding the behavior, predicting all possible failure mechanisms, and evaluating the ultimate strength by means of linearized buckling and geometrically and material nonlinear imperfection analyses with commercially available finite element software. Steps include setting up an appropriate finite element model, obtaining critical buckling

modes from linearized buckling analysis (LBA), and then using a linear combination of these modes as imperfection pattern for a geometrically and material nonlinear imperfection analysis (GMNIA).

Failure dominated by either material yielding or instability can thus be addressed, as well as interaction of failure modes. Equilibrium paths accompanied by snapshots of deformation and stress distribution at characteristic points are used for evaluating the results of the GMNI analysis, identifying the dominant failure modes as well as proposing and evaluating alternative strengthening measures.

Results of two case studies have been used to demonstrate this methodology, involving tall compression members and long-span beams with varying cross section, encountered in two steel roofs that have been recently designed in Greece.

Introduction

An accurate estimation of seismic ground motion plays an important role, in order to realize rational countermeasures against an earthquake disaster. This review focuses on seismic ground response analysis above engineering bedrock. As has been pointed out, in a large earthquake, a local concentration of seismic ground motion due to complex

ground structure often results in inducing severe damage to structures (e.g., see Liang and Sun (2000) for a review of relationships between complex ground structures and damage to structures). Although many countermeasures have been implemented, there remain sites in which local concentration of ground motion takes place; for example, a concentration of earthquake ground motion due to the complex ground structure caused severe damage to a buried gas pipeline network in the 2011 Tohoku Earthquake (Advisory Committee for Natural Resources and Energy et al. 2012). Because the impedance contrast between the engineering bedrock and the sedimentary layer is sharp, seismic ground motion is greatly amplified in sedimentary layers of complicated configuration showing nonlinear behavior. As a result, remarkably different seismic ground motion may be observed at even very close points. To prevent damage to structures due to locally concentrated seismic ground motion, a method is needed which can estimate ground motion amplification due to complex ground structure with high resolution and high accuracy.

A candidate for such an estimation method is observation that uses a dense network of seismographs. For example, a superdense seismograph network is operated in Tokyo (Shimizu et al. 2000), where the network of average distance between seismographs being 3 km has been installed for the real-time monitoring of earthquakes. However, it is difficult to estimate a local concentration of earthquake ground motion even with such a superdense seismograph network because the complex ground structure varies over distances of 10^{1-2} m. Also, it is difficult to estimate strain distribution because a seismograph can only observe point-wise wave profiles.

Another candidate is numerical simulation. The increase in ground structure data now enables the construction of a high-resolution three-dimensional (3D) numerical model that considers surface geometries and heterogeneities of the ground structure as faithfully as possible; from now on, this model is referred to as a “high-fidelity model.” Although 3D nonlinear seismic ground response analysis with the high-fidelity model can be expected to accurately estimate 3D local

site effects, it is not an easy task to conduct such numerical analyses because of the huge computation and modeling costs. As a result, numerical simulation with a simplified ground model is conventionally used. A representative analysis is a one-dimensional (1D) amplification analysis (e.g., SHAKE (Schnabel et al. 1972)). Because the 3D ground structure is approximated to a layered medium in the 1D amplification analysis, the 3D problem is reduced to the 1D problem. Stiffness and damping change momentarily, depending on shear strain due to 1D wave propagation. Although the 1D amplification analysis can estimate nonlinear seismic ground responses with less computational cost, it is not possible to estimate the local concentration which is caused by a 3D complex ground structure, by using the stratified-layer approximation. Recently, a two-dimensional (2D) nonlinear seismic ground response analysis has often been conducted for complex ground structure. It is quite natural that the 2D analysis gives more accurate estimations than the 1D analysis. However, a serious problem remains for the 2D analysis, with regard to selection of a suitable 2D cross section of the ground structure. Thus, 3D nonlinear seismic ground response analysis with a high-fidelity model is desirable.

Because numerical simulation performance and ground structure data have increased with recent advances in Information and Communications Technology (ICT), nonlinear seismic ground response analysis which computes a 3D high-fidelity model is becoming possible (e.g., Ichimura et al. (2014a, b)). Such an analysis enables estimation of the local concentration and strain distribution, which are difficult to observe. This review explains the detail and utility of the nonlinear seismic ground response analysis with a 3D high-fidelity model (Ichimura et al. 2014a).

Three-Dimensional Nonlinear Seismic Ground Response Analysis Method with a High-Fidelity Model

Because the finite element method (FEM) can accurately generate a 3D high-fidelity numerical model for complex ground structures and

accurately satisfy traction-free boundary conditions on the surface, the following nonlinear dynamic FEM with unstructured finite elements is used for the nonlinear seismic ground response analysis:

$$\left(\frac{4}{dt^2}\mathbf{M} + \frac{2}{dt}\mathbf{C}^n + \mathbf{K}^n\right)\delta\mathbf{u}^n = \mathbf{F}^n - \mathbf{Q}^{n-1} + \mathbf{C}^n\mathbf{v}^{n-1} + \mathbf{M}\left(\mathbf{a}^{n-1} + \frac{4}{dt}\mathbf{v}^{n-1}\right), \quad (1)$$

with

$$\begin{cases} \mathbf{Q}^n = \mathbf{Q}^{n-1} + \mathbf{K}^n\delta\mathbf{u}^n, \\ \mathbf{u}^n = \mathbf{u}^{n-1} + \delta\mathbf{u}^n, \\ \mathbf{v}^n = -\mathbf{v}^{n-1} + \frac{2}{dt}\delta\mathbf{u}^n, \\ \mathbf{a}^n = -\mathbf{a}^{n-1} - \frac{4}{dt}\mathbf{v}^{n-1} + \frac{4}{dt^2}\delta\mathbf{u}^n. \end{cases} \quad (2)$$

Here, $\delta\mathbf{u}$, $\mathbf{u}$, $\mathbf{v}$, $\mathbf{a}$, and $\mathbf{F}$ indicate the incremental displacement, displacement, velocity, acceleration, and external force vectors, respectively. $\mathbf{M}$, $\mathbf{C}$, and $\mathbf{K}$ indicate mass, damping, and stiffness matrices, respectively. dt and n indicate time increment and time step number, respectively. The Rayleigh damping matrix is used for $\mathbf{C}$; the element damping matrix $\mathbf{C}_e^n$ is calculated using the element mass matrix $\mathbf{M}_e$ and the element stiffness matrix $\mathbf{K}_e^n$ as

$$\mathbf{C}_e^n = \alpha\mathbf{M}_e + \beta\mathbf{K}_e^n.$$

Here, α and β are determined by solving the least squares equation,

$$\text{minimize} \left[\int_{f_{\min}}^{f_{\max}} \left(h^n - \frac{1}{2} \left(\frac{\alpha}{2\pi f} + 2\pi f \beta \right) \right)^2 df \right],$$

where $f_{\max}$, $f_{\min}$, and h^n indicate the maximum and minimum target frequencies and the damping ratio at time step n , respectively. Note that the damping matrix is calculated for every time step because the stiffness and damping ratio change by time step number, according to the constitutive relation of the ground material. Small elements are generated locally when modeling complex geometry with solid elements. Satisfying the

Courant condition when using an explicit time integration method (e.g., central difference method) for such small elements leads to small time increments and a huge computational cost. To resolve this problem, the Newmark- β method ($\beta = 1/4$, $\delta = 1/2$) is used for the time integration. Note that an explicit scheme is selected to compute the response robustly; an implicit scheme sometimes does not reach an accurate solution because of complex nonlinear constitutive relation. Thus, to verify the convergence of a solution, attention must be paid to the spatial and temporal discretization.

The most significant difference between the ordinary FEM analysis and the present nonlinear seismic ground response FEM analysis is the treatment of boundary conditions. Because the target domain is cut off from a half-infinite ground structure, half-infinite and absorbing conditions must be added on the bottom and side boundaries of the domain that describe the half-infinite continuity of the ground structure in the nonlinear seismic ground response FEM analysis. Several methods have been proposed, and one simple and effective method is based on damper and free motion ($\mathbf{u}^f$) on the side and bottom boundaries; $\mathbf{u}^f$ is computed based on the 1D wave theory, by applying the stress caused by $\mathbf{u}^f$ onto the side and bottom boundaries and by absorbing the scattered wave ($\dot{\mathbf{u}} - \dot{\mathbf{u}}^f$) on the side and bottom boundaries by the damper. This method can describe the half-infinite continuity with the assumption that the ground structure on the side boundaries is extended infinitely.

The computation is performed by repeating the following steps:

1. Compute stiffness and damping ratio for n -th time step with nonlinear constitutive relation using $\mathbf{u}^{n-1}$.
2. Compute $\mathbf{K}^n$ and $\mathbf{C}^n$ using stiffness and damping ratio for n th time step.
3. Compute $\delta\mathbf{u}^n$ by solving Eq. 1, and update values in Eq. 2 using $\delta\mathbf{u}^n$.

The bottlenecks of the nonlinear seismic ground response FEM analysis with a 3D high-fidelity model are the modeling cost and the

computation cost. For example, with the size of the target region of the order of $10^3 \times 10^3 \times 10^2$ m and a spatial resolution in the FE model of the order of $10^{-1\sim 0}$ m to satisfy the temporal resolution of a few Hz, the degrees of freedom (DOF) of the FE model become of the order of $10^{7\sim 9}$ and the time steps needed in the analysis would be of the order of $10^{3\sim 4}$. Because constructing such a large 3D FE model is difficult and the computational cost becomes enormous, it is still difficult to make a nonlinear, dynamic analysis for such a large problem. A fully automated modeling method that can generate elements of high quality is needed for constructing a 3D FE model of ground structures with large DOF. Here, the elements of high quality mean that the aspect ratio of the elements is small; an element with large aspect ratio behaves more stiffly, leading to a significant loss of accuracy in the analysis results. Although it is common to perform manual tuning to avoid elements of low quality, manual tuning of a huge model is extremely costly. Thus, a suitable method for the automated generation of an FE model is desirable. The remaining bottleneck is the large computational cost. The unknown in Eq. 1 is $\delta\mathbf{u}^n$; this is solved for each time step to obtain the time-history response of $\mathbf{u}$. Most of the computation time is spent solving the matrix equation of Eq. 1. Thus, a fast solver is also desirable.

Seismic Ground Motion Computed with a 3D High-Fidelity Model

Seismic ground motion is computed by nonlinear seismic ground response FEM analysis with a 3D high-fidelity model (see Ichimura et al. (2014a for details)). This example was an effort to reproduce the earthquake ground motion distribution in the 2011 Tohoku-Oki earthquake. The size of the target region modeled was 1,696 m in the east to west direction and 1,920 m in the north to south direction, where the soft sedimentary layers form a complex soil structure (see Fig. 1 for the 3D high-fidelity model of the target ground structures). The site is known to have had significantly larger

Nonlinear Seismic Ground Response Analysis of Local Site Effects with Three-Dimensional High-Fidelity Model, Fig. 1 Overall view of 3D ground structure model

observed seismic ground motion compared with that of nearby observation sites in past earthquake events. The modified Ramberg-Osgood model (Idriss et al. 1978) and the Masing rule (Masing 1926) were used as the nonlinear constitutive relation of soil material, and semi-infinite domain absorbing boundary conditions for the bottom and side boundaries of the domain were implemented, as explained above.

Here, a fully automated modeling method of Ichimura et al. (2009) with modifications was applied to constructing a 3D FE model, with the underground 3D soil structure being defined as a layered medium. A structured grid was used as background cells covering the target domain, and elements were made for each background cell. Here, the elements were generated in each cell so that they have low aspect ratios. This leads to a fully automated, robust method for making elements of high quality. Because the generation of elements in each cell is performed individually, it is suitable for parallelization, leading to fast element generation using parallel computation. First,

elements with linear-tetrahedral elements and cubic elements are generated, and the both types of elements are converted to second-order tetrahedral elements, leading to a 3D FE soil structure model consisting of only second-order tetrahedral elements. Also, a fast solver was implemented with the Block-Jacobi method, mixed-precision arithmetic, a geometric multigrid method, a predictor-corrector method, and parallel computing using hybrid parallelization MPI-OpenMP to reduce computational cost and shorten computation time.

Figure 2 shows a close-up view of the 3D FE soil structure model. It can be seen that the complex 3D geometry consisting of three soil layers is modeled faithfully. The minimum size of the second-order tetrahedral elements is 4 m. With 32,509,107 DOF, the number of tetrahedral elements and nodes are 7,779,048 and 10,836,369, respectively. Using this 3D FE model, a seismic response analysis with nonlinear dynamic FE analysis of 60,000 time steps with 0.005 s time increments was conducted. Here, Eq. 1 is solved for each time step with relative error less than 10×10^{-6} . A PC cluster with eight computing nodes was used, each computing node with dual hexa-core Intel Xeon X5680 CPUs, connected with the InfiniBand QDR network. Using this small system, an analysis can be conducted in only 1,107,495 s. On average, one step is solved in 18.46 s, which is fast enough, considering that a 32 million DOF matrix equation is solved. This analysis time would be expected to become much shorter as a faster computer or a larger computer system is used. Due to recent technological progress, a dynamic nonlinear FE analysis is becoming feasible for application to nonlinear soil response analyses.

The analysis results and observed data are compared at observation points shown in Fig. 3. The computed and observed waves matched well, although no tuning was performed on the input wave, soil parameters, or soil model. It is also possible to obtain better conformity using dense observation networks to tune models based on data obtained from such dense networks. The seismic ground motion distribution is evaluated at the surface. Figure 4a shows the maximum

Nonlinear Seismic Ground Response Analysis of Local Site Effects with Three-Dimensional High-Fidelity Model, Fig. 2 3D ground structure FE model. The close-up view of the region in the rectangle in Fig. 1

Nonlinear Seismic Ground Response Analysis of Local Site Effects with Three-Dimensional High-Fidelity Model, Fig. 3 Comparison of observed and computed waves

values of magnitude of displacement. It can be seen that the maximum displacement distribution has a high correlation with the depth of layer 1. To evaluate the strain in the axial direction (one of the damage indices for pipeline structure), the maximum values of principal strain in the whole time history are shown in Fig. 4b. Compared with the distribution of maximum displacement, it can be seen that estimating the distribution of strain from the ground structure is difficult; using numerical results of the seismic ground response analysis is effective for evaluating the distribution of strain. Two observation lines (A_0A_1 and B_0B_1) are set that imitate pipelines in parts of the model with nonuniform ground, and the axial strain is analyzed (see Fig. 1). Line A_0A_1 has a

V-shaped depth distribution in layer 1, which is similar to that reported in Tsukamoto et al. (1984), and Line B_0B_1 goes through the ground structure with a constantly increasing depth of layer 1, followed by a region with constant depth of layer 1. Figures 5 and 6 show the maximum axial strain and the soil structure under each line. The axial strain along line A_0A_1 is similar to the observed strain on buried pipelines in V-shaped surface soil layers reported in Figs. 1 and 2 of Tsukamoto et al. (1984). The response in the bedrock was small but became larger for the soft layer, with a nearly constant response in the center of the V-shaped valley. This leads to small axial strain in the center of the V-shaped valley and large strain between the bedrock and the soft

Nonlinear Seismic Ground Response Analysis of Local Site Effects with Three-Dimensional High-Fidelity Model, Fig. 4 Distribution of time-history maximum values of norm of displacement and maximum principal strain

Nonlinear Seismic Ground Response Analysis of Local Site Effects with Three-Dimensional High-Fidelity Model,

Fig. 5 Maximum axial displacement, maximum axial strain, and underground structure of line A_0A_1

soil layer. This phenomenon is the cause of the pipeline damage reported in Liang and Sun (2000) and Tsukamoto et al. (1984). The response of line B_0B_1 is more complex than that of A_0A_1 . Similar to line A_0A_1 , high axial strain occurs between the bedrock and the soft layers. On the other hand, a complex distribution of axial strain

can be observed from $x=900\text{--}1,200\text{ m}$, with a horizontally layered structure. This is because the soil structure around line B_0B_1 is complex and cannot be approximated by a two-dimensional structure, as shown in Fig. 6; the bedrock leans out from the northern side (see Fig. 1). From these observations, it can be seen

Nonlinear Seismic Ground Response Analysis of Local Site Effects with Three-Dimensional High-Fidelity Model,

Fig. 6 Maximum axial displacement, maximum axial strain, and underground structure of line B_0B_1

that nonuniform ground causes a complex ground motion distribution, suggesting that even 2D analyses could not be suitable to evaluating ground motion in some cases.

Summary

Increased ground structure data, computer performance, and numerical simulation abilities with advances in ICT now enable the execution of nonlinear seismic ground response analysis with a 3D high-fidelity model. Such analysis can accurately estimate earthquake ground motion in a complex ground structure model which is constructed from observed data. Even today, strain distribution can be estimated in a small computer environment; in the near future, such analyses are expected to become commonplace.

Introduction

The presence of nonlinearity in structural systems is inevitably linked to the dissipation of energy occurring either within particular components of the structure, such as joints or damper elements,

or as a result of exceeding material capacity which in turn leads to response that lies outside the usual assumption of the elastic range. Therefore, nonlinearity in the form of hysteretic behavior is commonly observed in structures subjected to significant levels of excitation such as earthquake, wind, or sea waves. Typically, the description of the restoring force that is associated with the behavior of such systems involves the use of nonlinear laws which render the governing system of equations a highly nonlinear one.

The task of joint parameter and state estimation for such systems is nontrivial as it requires the implementation of methods able to account for nonlinearity. The complexity of the problem is further increased when a real-time estimation is sought. The latter is quite commonly the case in structural health monitoring (SHM) implementations and in vibration control applications where the real-time feedback of the restoring force is necessary. In serving such a purpose, time domain identification methods constitute a class of methods particularly well suited for the online monitoring of dynamic systems. Numerous techniques have been proposed for time domain identification in civil engineering, including the more simplified autoregressive-moving average (ARMA) models, the least squares estimation (LSE) method, the Eigensystem realization algorithm (ERA), as well as the Bayesian approximation techniques, such as the observer/Kalman filter identification (OKID), the extended Kalman filter (EKF), the unscented Kalman filter (UKF), and the sequential Monte Carlo methods. Some of these techniques lend themselves more readily than others to problems where the system dynamics or the measurement equations are expressed as nonlinear functions of the states.

The EKF has by far been the most extensively used identification algorithm, for the case of nonlinear systems, over the past 30 years, and has been applied for a number of civil engineering applications, such as structural damage identification, parameter identification of inelastic structures, and so forth. It is based on the propagation of a Gaussian random variable (GRV) through the first-order linearization of the state-space model of the system. Despite

its wide use, the EKF is only reliable for systems that are almost linear on the time scale of the updating intervals. In what is presented herein, alternative techniques are presented that prove more efficient in handling higher-order nonlinearities. The UKF is an extension of the Kalman filter that does not require the calculation of Jacobians in order to linearize the state equations. Instead, the state is approximated by a GRV which is now represented by a set of carefully chosen points. These sample points completely capture the true mean and covariance of the GRV when propagated through the actual nonlinear system.

The sequential Monte Carlo method, also known as the particle filter (PF), is especially useful since it is capable of handling nonlinear systems described by non-Gaussian posterior probability of the state, as well as systems with non-Gaussian noise. This attribute makes the particular method quite attractive for SHM applications. The implementation concept is the approximation of the posterior probability of the state through the generation of a large number of samples that are appropriately weighted. Particle filters are essentially an extension to point-mass filters with the difference that the particles are no longer uniformly distributed over the state but instead concentrated in regions of high probability. A significant drawback is the fact that depending on the problem, a large number of samples may be required, thus rendering the PF analysis computationally expensive. Additionally, this method is faced with what is referred to as the sample impoverishment problem, which essentially refers to the loss of diversity among particles as the analysis progresses and can be quite pronounced when dealing with parameter identification problems, as is typically the case in SHM. In what follows, the workings of the methods are described and enhancements are presented to effectively treat issues arising in SHM applications.

As a literature note, a number of authors have implemented time domain modeling approaches within a monitoring framework (Juang and Pappa 1985; Juang et al. 1993; Smyth et al.

2002; Zhang et al. 2002; Nagarajaiah and Li 2004; Yang et al. 2006; Fraraccio et al. 2008). Additionally, several authors have experimented with the use of the EKF on nonlinear identification problems (Corigliano and Mariani 2004; Mariani and Corigliano 2005; Yun and Shinozuka 1980). The alternative nonlinear KF extension, i.e., the unscented Kalman filter, was first introduced in 1994 when J. Uhlmann suggested that rather than approximating the known system function through linearization, it might be beneficial to apply the exact nonlinear function to an approximating probability distribution (Julier and Uhlmann 1997). Wan and Van der Merwe (2000) further verified the validity of this proposal. In the case of SHM applications, Wu and Smyth have shown that the UKF is superior to the EKF for joint state and parameter estimation problems while proving more robust for increased measurement noise levels for high-dimensional systems (Wu and Smyth 2007). Chatzi and Smyth further demonstrated the potential of the UKF in balancing rapid estimation with high precision (Chatzi et al. 2010; Chatzi and Smyth 2009). The particle filter methods have also been widely applied for the case of nonlinear identification problems (Arulampalam et al. 2002; Chen et al. 2005; Ching et al. 2006; Nasrellah and Manohar 2011; Eftekhari et al. 2012).

The Dynamic Problem Formulation and the Optimal Bayesian Solution

Within a structural health monitoring framework, the target commonly is the tracking of dynamic response, described by the general continuous state-space formulation

$$\dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t)) + \mathbf{v}(t) \quad (1)$$

or by its discretized equivalent which is better suited for SHM implementations where information is provided via sampling at an interval Δt :

$$\mathbf{x}_k = \mathbf{F}(\mathbf{x}_{k-1}) + \mathbf{v}_{k-1} \quad (2)$$

The information on the system is provided through noisy observations of the form

$$\mathbf{y}_k = H(\mathbf{x}_k) + \boldsymbol{\eta}_k \quad (3)$$

where $\mathbf{x}_k \in \mathbb{R}^n$ is the **state variable vector** at time $t = k\Delta t$, $\mathbf{v}_k$ is the zero mean **process noise** vector with covariance matrix $\mathbf{Q}_k$, $\mathbf{y}_k \in \mathbb{R}^m$ is the current **observation vector**, and $\boldsymbol{\eta}_k$ is the **observation noise** vector with corresponding covariance matrix $\mathbf{R}_k$. It is worth noting that the regimes described herein do not require feedback from all of the system's degrees of freedom (dof's). Instead, we might have limited information drawn from few sensors on selected locations of the structure/system.

From a Bayesian perspective, the problem of determining the estimate of $\mathbf{x}_k$ based on the sequence of all available measurements up to time step k , $\mathbf{y}_k$, is a recursive one, involving the construction of a posterior PDF $p(\mathbf{x}_k|\mathbf{y}_{1:k})$. Assuming the prior distribution, $\mathbf{y}_0$, is known and that the required PDF $p(\mathbf{x}_{k-1}|\mathbf{y}_{1:k-1})$ at time $k-1$ is available, the prior probability $p(\mathbf{x}_k|\mathbf{y}_{1:k-1})$ can be obtained sequentially through:

Step 1 Prediction (Chapman-Kolmogorov Equation)

$$p(\mathbf{x}_k|\mathbf{y}_{1:k-1}) = \int p(\mathbf{x}_k|\mathbf{x}_{k-1})p(\mathbf{x}_{k-1}|\mathbf{y}_{1:k-1})d\mathbf{x}_{k-1} \quad (4)$$

The probabilistic model of the state evolution $p(\mathbf{x}_k|\mathbf{x}_{k-1})$, also referred to as transitional density, is defined by the process Eq. 2. Consequently, the measurement $\mathbf{y}_k$ is taken into account in formulating a posterior estimate through:

Step 2 Update (Bayesian Theorem)

$$p(\mathbf{x}_k|\mathbf{y}_{1:k}) = p(\mathbf{x}_k|\mathbf{y}_k, \mathbf{y}_{1:k-1}) = \frac{p(\mathbf{y}_k|\mathbf{x}_k)p(\mathbf{x}_k|\mathbf{y}_{1:k-1})}{p(\mathbf{y}_k|\mathbf{y}_{1:k-1})} \quad (5)$$

where the likelihood function $p(\mathbf{y}_k|\mathbf{x}_k)$ is completely defined by the observation Eq. 3.

Once the posterior PDF is known, the optimal estimate can be computed using different criteria, one of which is the minimum mean square error (MMSE) estimate. Although, the Bayesian solution is hard to compute analytically, the particle-based methods described herein in fact are approximations of this concept. For further details, the interested reader is pointed to the work of Ristic and Arulampalam (2004).

The Joint State and Parameter Estimation Problem

Within the context of SHM implementations, it is often the case that the parameters describing the model of the system are either unknown or known with some uncertainty. To this end, it is often desirable to additionally identify the time-invariant parameters of the system model. In a joint state and parameter estimation problem, the state vector of Eq. 1 is augmented in order to include the parameters to be identified, i.e.,

$$\tilde{\mathbf{x}} = \begin{bmatrix} \mathbf{x} \\ \boldsymbol{\theta} \end{bmatrix}, \quad \mathbf{x} \in \mathbb{R}^n, \quad \boldsymbol{\theta} \in \mathbb{R}^l \quad (6)$$

where $\boldsymbol{\theta}$ stands for the unknown parameter vector of dimension l . Given that this component is time invariant, Eq. 2 is modified as follows:

$$\tilde{\mathbf{x}}_k = \begin{bmatrix} \mathbf{x}_k \\ \boldsymbol{\theta}_k \end{bmatrix} = \begin{bmatrix} F(\mathbf{x}_{k-1}) \\ \boldsymbol{\theta}_{k-1} \end{bmatrix} + \begin{bmatrix} \mathbf{v}_{k-1} \\ \mathbf{v}_{\theta_{k-1}}^0 \end{bmatrix} \quad (7)$$

where $\mathbf{v}_{\theta_{k-1}}^0$ is an added process noise vector, relating to the time-invariant parameter components.

The Unscented Kalman Filter Method

The UKF approximates the state as a GRV, and therefore, assuming $N(\mathbf{x}; \boldsymbol{\mu}, \mathbf{P})$ is a Gaussian density with argument $\mathbf{x}$, mean $\boldsymbol{\mu}$, and covariance $\mathbf{P}$, the UKF relates to the two steps of the Bayesian approach Eqs. 4 and 5 through the following relationships:

$$\begin{aligned} p(\mathbf{x}_{k-1}|\mathbf{y}_{1:k-1}) &= N(\mathbf{x}_{k-1}; \hat{\mathbf{x}}_{k-1|k-1}, \mathbf{P}_{k-1|k-1}) \\ p(\mathbf{x}_k|\mathbf{y}_{1:k-1}) &= N(\mathbf{x}_k; \hat{\mathbf{x}}_{k|k-1}, \mathbf{P}_{k|k-1}) \\ p(\mathbf{x}_k|\mathbf{y}_{1:k}) &= N(\mathbf{x}_k; \hat{\mathbf{x}}_{k|k}, \mathbf{P}_{k|k}) \end{aligned} \quad (8)$$

In the classic Kalman filter formulation, outlined in the seminal paper by Kalman (1960), the prediction and update steps are formalized in a set of equations derived on the basis of linearity. In the case examined herein, the governing equations are nonlinear and a discretized equivalent is utilized for the propagation of the statistics of $\mathbf{x}_k \in \mathbb{R}^n$ through the system. The unscented transformation is used for this purpose which involves the computation of a set of discrete points, termed the sigma points, χ_k^i , with corresponding weights w_i . In order to do so, the original state vector is redefined as the concatenation of the original state vector and noise variables as $\mathbf{x}_{k-1}^\alpha = [\mathbf{x}_{k-1}^T \mathbf{v}_{k-1}^T \boldsymbol{\eta}_{k-1}^T]^T$. Then, the sigma points are distributed symmetrically around the mean $\hat{\mathbf{x}}_{k-1}^\alpha \in \mathbb{R}^L$ as follows:

$$\chi_{k-1} = \begin{bmatrix} \hat{\mathbf{x}}_{k-1}^\alpha & \hat{\mathbf{x}}_{k-1}^\alpha + \sqrt{(L+\lambda)\mathbf{P}_k^\alpha} \\ \hat{\mathbf{x}}_{k-1}^\alpha - \sqrt{(L+\lambda)\mathbf{P}_k^\alpha} \end{bmatrix} \quad (9)$$

Each of the columns of the above matrix corresponds to a sigma point vector $\chi_{k-1}^i \in \mathbb{R}^L$ with components corresponding to the state, process, and measurement noise, respectively, and $\mathbf{P}_k^\alpha$ is the corresponding augmented covariance vector, incorporating the process and observation noise components:

$$\chi_{k-1}^i = \begin{bmatrix} \chi_{k-1}^{x,i} \\ \chi_{k-1}^{v,i} \\ \chi_{k-1}^{\eta,i} \end{bmatrix}, \quad \mathbf{P}_{k-1}^\alpha = \begin{bmatrix} \mathbf{P}_{k-1} & 0 & 0 \\ 0 & \mathbf{Q}_{k-1} & 0 \\ 0 & 0 & \mathbf{R}_{k-1} \end{bmatrix} \quad (10)$$

The weights for the state and covariance components of the sigma point vector are calculated as

$$\begin{aligned} w_0^x &= \frac{\lambda}{L+\lambda}, w_0^p = \left[\frac{\lambda}{L+\lambda} + (1-\alpha^2+\beta) \right] \\ w_i^x &= w_i^p = \frac{1}{2(L+\lambda)}, \quad i = 1, \dots, 2L \end{aligned} \quad (11)$$

where α, κ, β are the KF parameters, $\lambda = \alpha^2(L+\kappa) - L$ is a scaling parameter. α and κ are scaling

factors (for a two-dimensional state vector, $\kappa = 0$ is optimal), and β is related to the distribution (equals to 2 for Gaussian priors). Finally, L is the dimension of the augmented state vector.

Step 1 UKF Prediction

The state and process noise components of the sigma point vectors are propagated through the nonlinear function $F(\mathbf{x}_k)$ without any need for linearization:

$$\chi_{k|k-1}^{x,i} = F\left(\chi_{k-1}^{x,i}, \chi_{k-1}^{v,i}\right), \quad i = 0, \dots, 2L \quad (12)$$

The discrete set of the sample points, $\chi_{k|k-1}^{x,i} \in \mathbb{R}^n$, is utilized to derive a representation of the prior density $p(\mathbf{x}_k | \mathbf{y}_{1:k-1})$. The prior mean and covariance are approximated as the weighted sample mean and covariance of the prior sigma points and the time update step is continued as follows:

$$\hat{\mathbf{x}}_{k|k-1} = \sum_{i=0}^{2L} w_i^x \chi_{k|k-1}^{x,i} \quad (13)$$

$$\mathbf{P}_{k|k-1} = \sum_{i=0}^{2L} w_i^p \left[\chi_{k|k-1}^{x,i} - \hat{\mathbf{x}}_{k|k-1} \right] \left[\chi_{k|k-1}^{x,i} - \hat{\mathbf{x}}_{k|k-1} \right]^T \quad (14)$$

Step 2 UKF Update

An estimate of the observation vector (reflecting the measured quantities) may then be approximated as

$$\hat{\mathbf{y}}_{k|k-1} = \sum_{i=0}^{2L} w_i^x H\left(\chi_{k|k-1}^{x,i}, \chi_{k-1}^{\eta,i}\right) \quad (15)$$

where the state and observation noise components of the sigma point vectors are propagated through the nonlinear observation function $H(\mathbf{x}_k)$. Finally, the posterior estimate $\hat{\mathbf{x}}_{k|k}$ is obtained as the weighted sum of the prior $\hat{\mathbf{x}}_{k|k-1}$ and the measurement residual, $\mathbf{y}_k - \hat{\mathbf{y}}_{k|k-1}$, which reflects the discrepancy between the predicted measurement and the actual measurement. The Kalman gain matrix at time step k , $\mathbf{K}_k$, acts as the weighing factor:

$$\hat{\mathbf{x}}_k = \hat{\mathbf{x}}_{k|k} = \hat{\mathbf{x}}_{k|k-1} + \mathbf{K}_k (\mathbf{y}_k - \hat{\mathbf{y}}_{k|k-1}) \text{ where } \mathbf{K}_k = \mathbf{P}_k^{xy} (\mathbf{P}_k^{yy})^{-1}$$

$$\text{with } \begin{cases} \mathbf{P}_k^{yy} = \sum_{i=0}^{2L} w_i^p \left[H(\mathbf{x}_{k|k-1}^{x,i}) - \hat{\mathbf{y}}_{k|k-1} \right] \left[H(\mathbf{x}_{k|k-1}^{x,i}) - \hat{\mathbf{y}}_{k|k-1} \right]^T \\ \mathbf{P}_k^{xy} = \sum_{i=0}^{2L} w_i^p \left[\mathbf{x}_{k|k-1}^{x,i} - \hat{\mathbf{x}}_{k|k-1} \right] \left[H(\mathbf{x}_{k|k-1}^{x,i}) - \hat{\mathbf{y}}_{k|k-1} \right]^T \end{cases} \quad (16)$$

The posterior state covariance is also calculated as

$$\mathbf{P}_k = \mathbf{P}_{k|k} = \mathbf{P}_{k|k-1} - \mathbf{K}_k \mathbf{P}_k^{yy} \mathbf{K}_k^T \quad (17)$$

Figure 1 illustrates the workings of the unscented Kalman filter.

The unscented Kalman filter, as its linear equivalent, is quite sensitive to the selection of the initial state covariance $\mathbf{P}_0$ as well as the noise covariance matrices $\mathbf{Q}_k$, $\mathbf{R}_k$. As in the linear KF case, the autocovariance least-squares (ALS) technique (Rajamani and Rawlings 2009) can be utilized which employs autocovariances of routinely operating data for estimating the noise covariance matrices.

Gaussianity is made for the state and noise components. The general particle filter, however, does not make any prior assumption on the state distribution. Instead, the posterior probability density function (PDF), $p(\mathbf{x}_k | \mathbf{y}_{1:k})$, is approximated via a set of random samples, also known as support points $\mathbf{x}_k^i$, $i = 1, \dots, N$, with associated weights w_k^i . This means that the probability density function at time k can be approximated as follows:

$$p(\mathbf{x}_k | \mathbf{y}_{1:k}) = \sum_{i=1}^N w_k^i \delta(\mathbf{x}_k - \mathbf{x}_k^i) \quad (18)$$

where

$$w_k^i \propto \frac{p(\mathbf{x}_k^i | \mathbf{y}_{1:k})}{q(\mathbf{x}_k^i | \mathbf{y}_{1:k})} \quad (19)$$

N

The Particle Filter Method

The unscented Kalman filter is in fact a particular case of the particle filter where the assumption of

where $\mathbf{x}_k^i$ are the N samples drawn at time step k from the **importance density function** $q(\mathbf{x}_k^i | \mathbf{y}_{1:k})$. The appropriate selection of this

Nonlinear System Identification: Particle-Based Methods, Fig. 1 The unscented Kalman filter process for a two-dimensional state

function constitutes a fundamental consideration in this class of methods as explained next.

Using the state-space assumptions (1st-order Markov process/observational independence for a given state), the importance weights can be estimated recursively by

$$w_k^i \propto w_{k-1}^i \frac{p(\mathbf{y}_k | \mathbf{x}_k^i) p(\mathbf{x}_k^i | \mathbf{x}_{k-1}^i)}{q(\mathbf{x}_k^i | \mathbf{x}_{k-1}^i, \mathbf{y}_k)} \quad (20)$$

where $p(\mathbf{x}_k^i | \mathbf{x}_{k-1}^i)$ is the transitional density, defined by the process Eq. 2, and $p(\mathbf{y}_k | \mathbf{x}_k)$ is the likelihood function, defined by the observation Eq. 3. As the number of samples increases, this sequential Monte Carlo approach becomes an equivalent representation to the function description of the PDF and the solution approaches the optimal Bayesian estimate.

The Importance Density Function

An important issue in the implementation of particle filters is the selection of the importance density. It has been proved that the optimal importance density function that minimizes the variance of the true weights is given by

$$\begin{aligned} q(\mathbf{x}_k | \mathbf{x}_{k-1}^i, \mathbf{y}_{1:k})_{\text{opt}} &= p(\mathbf{x}_k | \mathbf{x}_{k-1}^i, \mathbf{y}_k) \\ &= \frac{p(\mathbf{y}_k | \mathbf{x}_k, \mathbf{x}_{k-1}^i) p(\mathbf{x}_k | \mathbf{x}_{k-1}^i)}{p(\mathbf{y}_k | \mathbf{x}_{k-1}^i)} \end{aligned} \quad (21)$$

However, sampling from $p(\mathbf{x}_k | \mathbf{x}_{k-1}^i, \mathbf{y}_k)$ might not be straightforward, leading to the use of the transitional prior as the importance density function which greatly simplifies the analysis process:

$$q(\mathbf{x}_k | \mathbf{x}_{k-1}^i, \mathbf{y}_{1:k}) = p(\mathbf{x}_k | \mathbf{x}_{k-1}^i) \quad (22)$$

This essentially means that at time step k , the samples $\mathbf{x}_k^i$ are drawn from the transitional density, which is entirely defined by the process equation. Additionally, Eq. 20 yields

$$w_k^i = w_{k-1}^i p(\mathbf{y}_k | \mathbf{x}_k^i) \quad (23)$$

Therefore, the selection of the importance weights is essentially dependent on the likelihood

of the error between the estimate and the actual measurement, as this is defined by the observation function H and the assumed properties of the observation noise $\boldsymbol{\eta}_k$.

The weights are then normalized so that their sum equals unity. In relating this process to the prediction and update steps referenced earlier, a two-stage methodology is once again derived where:

Step 1 PF Prediction

Given the value of the N discrete state vectors (particles), at the previous time step, $\mathbf{x}_{k-1}^i$, these are propagated through the process equation of the dynamic system in order to yield a prior estimate:

$$\mathbf{x}_{k|k-1}^i = F(\mathbf{x}_{k-1}^i) + \mathbf{v}_{k-1}, \quad i = 1, \dots, N \quad (24)$$

Step 2 PF Update

The evaluation of the importance weights through the use of the likelihood function essentially constitutes the measurement update step, leading to the calculation of the posterior estimate through the weighted mean of the sample points:

$$\hat{\mathbf{x}}_k = \sum_{i=1}^N w_k^i \mathbf{x}_{k|k-1}^i \quad (25)$$

The Problem of Degeneracy and the Resampling Process

A second issue pertaining to the implementation of particle filters (PFs) is that of **degeneracy**, meaning that after some time steps, importance weights are unevenly distributed; thus, considerable computational effort is spent on updating particles with “trivial” contribution to the approximation of $p(\mathbf{x}_k | \mathbf{y}_{1:k})$. This may create numerical instabilities and calls for appropriate treatment. In quantifying this divergence, a measure of degeneracy has been specified, also known as the effective sample size:

$$N_{\text{eff}} = \frac{1}{\sum_{i=1}^N (w_k^i)^2} \quad (26)$$

Nonlinear System Identification: Particle-Based Methods,

Fig. 2 The process of resampling: the uniformly distributed random variable u_i maps into index j ; thus, the corresponding particle $\mathbf{x}_k^j$ is likely to be selected due to its considerable weight w_k^j

Resampling is a technique developed for the tackling of degeneracy. It discards those particles with negligible weights and enhances the ones with more significant weights. Resampling takes place when N_{eff} falls below some user-defined threshold N_T . A particle is more likely to be selected as a member of the remaining set, if it corresponds to a higher weight as schematically shown in Fig. 2.

The workings of the various stages of the particle filter algorithm are illustrated in Fig. 3.

The Problem of Sample Impoverishment

The use of the resampling technique however is known to lead to other problems, relating to the loss of diversity of particles. As the higher-weight particles are duplicated, diversity is lost leading to the **sample impoverishment (or particle depletion) phenomenon**. Such a phenomenon is more likely to occur when the process noise levels are low and is particularly problematic in the case of joint state and parameter estimation. As demonstrated in section “[The Joint State and Parameter Estimation Problem](#)” and in the example that follows, in such a case the state vector is augmented to include the unknown, but time-invariant (constant) system parameters yielding state components with minimal variability throughout the analysis process. Since the addition of a significant amount of process noise would lead to algorithm convergence problems and instability issues, one typically needs to resort to the use of a large number of particles. Although, both the UKF and PF present the advantage of parallel implementation, the use of an excessive number of particles inevitably incurs

a significant computational cost which can be a major disadvantage. The UKF is free of such a problem as the conditioning of the state via the Kalman gain induces a variability in the evolution of the parameter components $\boldsymbol{\theta}$ of the augmented state vector $\tilde{\mathbf{x}}$ of Eq. 7.

More information on the selection of the importance weights based on importance sampling can be found in Doucet et al. (2001), Bergman (1999), and Bergman et al. (2001).

The Particle Filter with Mutation

In order to tackle the sample impoverishment problem, Chatzi and Smyth (2013) proposed an enhancement of the PF, termed the particle filter with mutation (MPF), which incorporates a mutation operator in the resampling process. **Mutation** is a process typically used in genetic algorithms (GAs) where it serves as a means of maintaining diversity among the members of a population. Within the framework of GAs, mutation is typically enforced under two regimes, the *creep mutation* and the *jump mutation*. Jump mutations involve random modifications in the binary encoding of the system’s variables, whereas creep mutation takes place in the real number representation of the variables (i.e., the phenotype). The operation implemented in the MPA scheme resembles the creep mutation process.

In SHM implementations or system identification problems where the estimation of system parameters is required, the state vector is commonly augmented in order to include these

Nonlinear System Identification: Particle-Based Methods, Fig. 3 The particle filter implementation steps

parameters as in Eq. 6. Consequently, the state-space equations are also expanded to include the zeroth derivative equations that enforce the time invariance of those parameters, which are considered as constants. Equation 7 reflects with the discrete time equivalent, indicating the time invariance of the parameter components. Hence, especially in the case of higher complexity problems, the initial particle selection space needs to be appropriately spanned and quite densely sampled in order to achieve an efficient parameter estimate. In other words the initial sample space needs to include seeds sufficiently close to the true parameter values for a successful prediction. In order to cope with this restriction, the MPF algorithm features a twofold innovation, enforced during the resampling step, i.e., when the effective sample size, N_{eff} , drops below a certain threshold.

Propagating the Weighted Estimate of the State

Firstly, part of the formerly unfit particles is replaced in step k by the prior estimate of the weighted mean of the state, obtained as $\hat{\mathbf{x}}_{k|k-1} = F(\hat{\mathbf{x}}_{k-1})$. Replacement is performed under a uniform probability, p_e , i.e., if $\text{rand} < p_e$, where rand is a uniformly distributed random number, then replacement takes place; otherwise, the particles remain unchanged. Function F is the state-space function of the process Eq. 2. In this manner, the actual value of the weighted estimate is incorporated in the particles and propagated through the nonlinear system. Formerly, the optimal estimate would only appear as the weighted result and the actual fitness for that particle was not explicitly evaluated at any step of the algorithm. For strongly nonlinear systems, this may lead to imprecise estimations.

Nonlinear System Identification: Particle-Based Methods, Fig. 4 The particle filter with mutation implementation steps

Mutation of the Time Invariant Components

Secondly, after the formerly unfit particles have been replaced by either particles of more significant weight (standard resampling) or by the propagated value of $\hat{x}_{k-1}$, their time-invariant components are mutated. Mutation takes place by shifting the parameter components by a random amount using a mutation probability p_m . Both the mutation probability and the extent of the shifting interval can be user specified. The mutated particles are assigned a weight that is inversely proportional to the relative difference between the mutated vector and the original one ("parent" vector) according to the following relationship:

$$w_k^i = \frac{1}{N} \frac{1}{\left\| \frac{\Delta x_k^i}{x_k^i} \right\| + 1} \quad (27)$$

whereas the weights of the non-mutated resampled particles remain equal to $w_k^i = \frac{1}{N}$.

In expression Eq. 27, Δx_k^i is the difference between the mutated vector and the parent one and $\| \cdot \|$ is the L_2 norm. The full set of weights is then once again normalized before proceeding to the next time step. A graphical representation of the MPF, relating it to the stages previously outlined for the standard PF, is displayed in Fig. 4.

As a literature note, the blending of the standard PF with evolutionary concepts has only very recently been explored in the literature. Akhtar et al. (2011) propose a Particle Swarm Optimization accelerated Immune Particle Filter (PSO-ac-IPF). Park et al. (2007) propose the so-called genetic filter which involves a standard genetic algorithm step (with all three GA operators, i.e., crossover, mutation, and selection) in place of standard resampling. Similarly, Kwok et al. (2005) employ the crossover operator to what they call the evolutionary particle filter.

The drawback of the previous approaches is that they more or less incorporate a GA or PSO

Nonlinear System Identification: Particle-Based Methods,

Fig. 5 One floor shear-frame structure with a Bouc-Wen-type material nonlinearity

(Particle Swarm Optimization) step in the process, often requiring several loops that might significantly delay what is already a relatively lengthy estimation procedure. More recently, Yu et al. (2010) have suggested the use of simply the mutation operator for an adaptive mutation PF. The scheme proposed by Yu et al. quite resembles the earlier-mentioned notion of adding artificial process noise to the state vector.

Application: Joint State and Parameter Estimation for a Nonlinear Shear-Frame Structure

The approaches outlined above are tested on the real-time system identification of a nonlinear single degree of freedom (sdf) system. The system is assumed to describe the hysteretic response of a one storey shear-type frame building. This type of structure is described by a single translational degree of freedom in the elastic case. In the present example, the structure exhibits material nonlinearity when subjected to a ground motion, simulating earthquake excitation. As noted in

Fig. 5, this type of system is equivalent to a mass-spring-dashpot-hysteretic element system. The Bouc-Wen model is used in order to account for nonlinear hysteretic response, which involves an additional hysteretic degree of freedom, henceforth denoted as $z(t)$.

Using the Bouc-Wen model, it is quite straightforward to compile the system's governing equations of motion. In fact the Bouc-Wen enables an elegant and concise formulation of the nonlinear phenomenon of hysteresis. For reasons of simplicity, dependence on time is not explicitly denoted in the expressions that follow:

$$\begin{aligned} m\ddot{x} + c\dot{x} + \alpha kx + (1 - \alpha)kz &= -m\ddot{x}_g \\ \dot{z} &= \dot{x} - \beta|\dot{u}||z|^{n-1}z - \gamma\dot{u}|z|^n \end{aligned} \quad (28)$$

Additionally, we assume that we have measurements of the system's absolute acceleration, via the use of appropriate accelerometer sensors. Since the aim is the joint state and parameter identification, as the nonlinear dof $z(t)$ cannot be measured, the system is cast into the following state-space form:

$$\dot{\mathbf{x}}(t) = \begin{bmatrix} \dot{x}(t) \\ -\frac{c}{m}\dot{x}(t) - \alpha\frac{k}{m}x(t) - (1 - \alpha)\frac{k}{m}z(t) - \ddot{x}_g(t) \\ \dot{x}(t) - \beta|\dot{u}(t)||z(t)|^{n-1}z(t) - \gamma\dot{u}(t)|z(t)|^n \\ 0 \\ 0 \\ 0 \\ 0 \end{bmatrix} + \mathbf{v}(t) \quad (29)$$

Nonlinear System Identification: Particle-Based Methods,
Fig. 6 The input ground acceleration: Northridge earthquake

where $\mathbf{v} \in \mathbb{R}^8$ is the process noise vector, and $\tilde{\mathbf{x}} \in \mathbb{R}^8$ is the augmented vector that includes the displacement x , velocity $\dot{x}$, hysteretic dof z , as well as the stiffness k , damping c , and Bouc-Wen parameter constants α, β, γ . Hence, the parameter vector $\boldsymbol{\theta} \in \mathbb{R}^5$ is defined as $\boldsymbol{\theta} = [k \ c \ \alpha \ \beta \ \gamma \ n]^T$ and

$$\tilde{\mathbf{x}} = [x \ \dot{x} \ z \ k \ c \ \beta \ \gamma \ n]^T \quad (30)$$

The state-space (process) equation is complimented by the accompanying measurement (observation) equation:

$$\begin{aligned} y(t) = \ddot{x}_{tot}(t) = & -\frac{c}{m}\dot{x}(t) - \alpha\frac{k}{m}x(t) \\ & - (1 - \alpha)\frac{k}{m}z(t) + \boldsymbol{\eta}(t) \end{aligned} \quad (31)$$

where $\boldsymbol{\eta} \in \mathbb{R}$ is the measurement noise vector. The process equation can be brought into a discrete form by implementing a simple integration scheme. In order to keep the process online, a simple Euler scheme is implemented herein and proves to be sufficient for our purposes.

The actual response of the system is numerically generated using $k = 9$, $m = 1$, $c = .25$, $\alpha = 0.2$, $\beta = 2$, $\gamma = 1$ & $n = 2$ and the implemented ground motion is a scaled

record of the Northridge earthquake (1994) shown in Fig. 6. Furthermore, the discretization is performed using a sampling frequency of 100 Hz which is also the sampling frequency of the input ground motion. The analysis is performed for a total of 20 s.

The particle-based algorithms outlined in the previous sections are implemented, namely, the UKF, the PF, and the MPF algorithm. The UKF employs 21 particles ($=2*10 + 1$), the PF requires 5,000 particles for achieving admissible accuracy, and the MPF is run using 800 particles. The tuning parameters of the mutation operator for the PF are selected as $p_e = 0.2$, $p_m = 0.1$.

A Gaussian, process noise level of 0.1 % RMS noise-to-signal ratio is assumed, while the observation noise corresponds to approximately 10 % RMS. No process noise is added for the time-invariant parameter components. The addition of some minor noise could improve parameter estimation for the PF; however, it might also lead to instabilities and non-converging behavior. The observation noise is chosen so as to reflect a realistic instrumentation noise level, whereas the process noise is kept to a low level indicating confidence that the observed system can be described by this type of a model formulation.

Figure 7 illustrates the estimated state evolution for the three filters. It is already obvious that the standard particle filter (PF) underperforms

Nonlinear System Identification: Particle-Based Methods, Fig. 7 Estimated versus actual state evolution

and is not able to accurately track the system's states with a relative error of $\sim 20\%$ for the displacement estimate. The accuracy of the other two filters is almost identical and very close to the actual time history, with a relative error of $\sim 3.5\%$ for the UKF and $\sim 3\%$ for the MPF. As verified by the parameter estimation results, summarized in Figs. 8 and 9, the PF fails to accurately identify the true parameter values, as a result of the sample impoverishment problem outlined in section "The Problem of Sample Impoverishment." The use of the mutation operator for the particle filter with mutation (MPF) on the other hand alleviates this problem. The latter is schematically presented in Figs. 10 and 11 where it is obvious that, for the PF, the particle group eventually degenerates to a single parameter set for the time-invariant parameters. The use of the mutation operator for the MPF succeeds in maintaining the diversity of the population with a small scatter around the finally identified value, which prevents the algorithm from reaching a premature convergence.

From a computational cost perspective, in this quite simple sdof problem, all of the suggested

methods can be implemented in real time, i.e., on the fly, as data is acquired. The computational time required for the whole analysis on a 4 core CPU is of the order of 1.0 s for the UKF, 5.7 s for the PF (5,000 particles), and 1.5 s for the MPF. The required time would of course increase for a higher dimensionality; nonetheless, one of the benefits of particle-based regimes is the fact that they can be implemented in parallel, as the particle evaluations are mutually independent.

Summary

This reference entry describes the use of particle-based methods for joint state and parameter identification of a structural system for SHM purposes. This class of methods is adopted in order to tackle the difficulties arising due to the nonlinear nature of the physical system and the uncertainty related to our knowledge of the system characteristics. The workings of each method are described, and the advantages, limitations, and enhancements of the presented approaches

Nonlinear System Identification: Particle-Based Methods, Fig. 8 Estimated versus Actual Material Parameter evolution

Nonlinear System Identification: Particle-Based Methods, Fig. 9 Estimated versus actual Bouc-Wen parameter evolution

are presented and discussed. As demonstrated, the use of particle-based techniques enables the real-time tracking of state evolution and the accurate identification of unknown system parameters

in a robust and reliable manner. The benefits would be even more pronounced if a parallel processing regime were adopted, drastically cutting down the required computational time.

- Dynamic loading due to wind gusts
- Any kind of irregular train of impacts or shocks

As the occurrence (arrival) times of the loads are random, their mathematically sound characterization is in terms of stochastic point (random counting) processes. The most fundamental and the simplest of such processes is a Poisson process. However, it is known that the Poisson process is an adequate model of a random train of events if the events are rare. Otherwise, other models, for example, the renewal processes, are more suitable. The impulse process excitation (or the random train of impulses) may be driven by different processes. If it is driven by a Poisson process, the state vector of the dynamic system is a nondiffusive, so-called Poisson-driven, Markov process. Pertinent mathematical tools such as generalized Itô's differential rule or Kolmogorov–Feller integrodifferential equation may be used. However, if the impulse process is non-Poisson (i.e., it is driven by a counting process other than Poisson), the state vector of the dynamic system is not a Markov process, and no mathematical tools may be directly applied. Then the problem has to be converted into a Markov one. Here-with it is explained how it may be achieved with the aid of two exact methods. The first one is the method of augmentation of state vector by additional state variables, which are pure-jump stochastic processes. In this approach the augmented state vector becomes a nondiffusive, Poisson-driven, Markov process, and the differential equations for response moments may be derived. In the second method, the state vector of the dynamic system is augmented by Markov states of an auxiliary, pure-jump stochastic process. This approach allows to obtain the set of integrodifferential equations governing the joint probability density of the state vector and also the differential equations for response moments. Two example non-Poisson impulse processes are considered: an Erlang renewal impulse process and the process driven by two independent Poisson processes.

Introduction

Dynamic loads are adequately idealized as discontinuous stochastic processes, or random trains of loading events, in the following problems:

- Behavior of a vehicle traveling over a very rough road: impacts or shocks, due to sudden humps or holes
- Impact loads on booms of bucket-wheel excavators used in opencast mining engineering
- Moving loads on a bridge due to highway traffic

Stochastic Point Processes

Specification of a Random Counting Process

Let $N(t)$ denote a random counting process, or a random variable, specifying the number of events (or time points) in an interval $[0, t]$, i.e., excluding the event that possibly occurs at the time instant t . Consequently the sample paths of $N(t)$ are ever-increasing step (pure-jump) functions, which are left continuous with right limits. Strictly speaking, an additional assumption $\Pr\{N(0) = 0\} = 1$ should also be imposed. The occurrences of events are not, in general, assumed to be independent. The increment $dN(t)$ of the counting process during an infinitesimal time interval $[t, t + dt]$, denoted conventionally as $dN(t)$, is defined as $dN(t) = N(t + dt) - N(t)$.

The point process is *regular* or *orderly*, if the probability governing the counting measure satisfies the following condition:

$$\sum_{k \geq 1} \Pr\{dN(t) = k\} = O(dt^2), \quad (1)$$

which means that in the infinitesimal time interval, there can only occur, with nonzero probability, one event or no event.

Let the disjoint infinitesimal time intervals $[t_i, t_i + dt_i]$, $i = 1, 2, \dots, n$ be chosen from the interval $[0, t]$. Product density functions are defined as follows (Srinivasan 1974):

$$f_n(t_1, t_2, \dots, t_n) dt_1 \dots dt_n = E \left[\prod_{i=1}^n dN(t_i) \right]. \quad (2)$$

Equivalently, if the point process is regular, the n th degree product density function $f_n(t_1, \dots, t_n)$ represents the probability that one event occurs in each of disjoint intervals $[t_i, t_i + dt_i]$, irrespective of other events in the interval $[0, t]$; thus,

$$f_n(t_1, t_2, \dots, t_n) dt_1 \dots dt_n = \Pr \left\{ \bigwedge_{i=1}^n dN(t_i) = 1 \right\}. \quad (3)$$

$t_1 \neq t_2 \neq \dots \neq t_n.$

In what follows the attention is confined to regular or orderly point processes. In particular,

$$\Pr\{dN(t) = 1\} = f_1(t)dt, \quad (4)$$

where $f_1(t)$ is the product density of degree one. The regularity assumption Eq. 1 implies that

$$\Pr\{dN(t) = 0\} = 1 - f_1(t)dt + O(dt^2), \quad (5)$$

$$E[dN(t)] = f_1(t)dt + O(dt^2), \quad (6)$$

and

$$E[\{dN(t)\}^n] = f_1(t)dt + O(dt^2), \quad (7)$$

for arbitrary n .

Product density of degree one $f_1(t)$ represents the mean rate of occurrence of events (mean arrival rate). It should be noted that $f_1(t)$ is not a probability density; its integration over the whole time interval $[0, t]$ yields an expected number of events in this interval, which usually is not equal to one:

$$\begin{aligned} \int_0^t f_1(\tau) d\tau &= \int_0^t E[dN(\tau)] = E \left[\int_0^t dN(\tau) \right] \\ &= E[N(t)]. \end{aligned} \quad (8)$$

Product density of degree two, satisfying the relationship

$$f_2(t_1, t_2) dt_1 dt_2 = E[dN(t_1) dN(t_2)], \quad t_1 \neq t_2, \quad (9)$$

specifies the correlation between arrival rates at two different time instants t_1, t_2 (or the correlation of increments of the counting measure $N(t)$ on disjoint infinitesimal time intervals).

If k out of n time instants are set equal, i.e., $t_{j_1} = t_{j_2} = \dots = t_{j_k}$, or k out of n infinitesimal intervals all overlap, the product density of degree n degenerates to $(n - k + 1)$ th degree product density; thus,

$$\begin{aligned}
 E \left[\prod_{i=1}^n dN(t_i) \right] \Big|_{t_{i_1}=\dots=t_{i_k}} &= E \left[\prod_{i=1}^n dN(t_i) \{dN(t_{j_1})\}^k \right] \\
 i \neq j_r, \quad r &= 1, \dots, k \\
 &= f_{n-k+1}(t_1, \dots, t_n, t_{j_1}) dt_1 \dots dt_n dt_{j_1}.
 \end{aligned} \tag{10}$$

For example,

$$\begin{aligned}
 E[dN(t_1)dN(t_2)]|_{t_1=t_2} &= E \left[\{dN(t_1)\}^2 \right] \\
 &= f_1(t)dt.
 \end{aligned} \tag{11}$$

Joint density function, defined as

$$f_k(t_1, \dots, t_k) = \sum_{n=k}^{\infty} \frac{1}{(n-k)!} \underbrace{\int_0^t \dots \int_0^t}_{(n-k)\text{-fold}} \pi_n(t_1, \dots, t_k, t_{k+1}, \dots, t_n) dt_{k+1} \dots dt_n \tag{13}$$

$$\pi_k(t_1, \dots, t_k) = \sum_{n=k}^{\infty} \frac{(-1)^{n-k}}{(n-k)!} \underbrace{\int_0^t \dots \int_0^t}_{(n-k)\text{-fold}} f_n(t_1, \dots, t_k, t_{k+1}, \dots, t_n) dt_{k+1} \dots dt_n. \tag{14}$$

The probability that exactly n events occur in the time interval $[0, t]$ is evaluated as (Srinivasan 1974)

$$\Pr\{N(t) = n\} = \frac{1}{n!} \underbrace{\int_0^t \dots \int_0^t}_{n\text{-fold}} \pi_n(t_1, t_2, \dots, t_n) dt_1 dt_2 \dots dt_n. \tag{15}$$

Moreover, the correlation functions of the n th degree are defined in terms of product densities as (Stratonovich 1963)

$$\begin{aligned}
 g_1(t) &= f_1(t), \\
 g_2(t_1, t_2) &= f_2(t_1, t_2) - f_1(t_1)f_1(t_2), \\
 g_3(t_1, t_2, t_3) &= f_3(t_1, t_2, t_3) - 3\{f_1(t_1)f_2(t_2, t_3)\}_s \\
 &\quad + 2f_1(t_1)f_1(t_2)f_1(t_3),
 \end{aligned} \tag{16}$$

$$\begin{aligned}
 &\pi_n(t_1, t_2, \dots, t_n) dt_1 dt_2 \dots dt_n \\
 &= \Pr \left\{ \bigwedge_{i=1}^n dN(t_i) = 1 \wedge N(t) = n \right\},
 \end{aligned} \tag{12}$$

specifies the probability that one event occurs in each of disjoint intervals $[t_i, t_i + dt_i]$ and there are no other events in the whole time interval $[0, t]$, i.e., that there are exactly $N(t) = n$ events.

The following relationships between the product density and the joint density functions hold (Srinivasan 1974):

where $\{\cdot \cdot \cdot\}_s$ denotes the symmetrizing operation, i.e., the arithmetic mean of all terms similar to the one in brackets and obtained by all possible permutations of t_1, t_2, t_3 . For example,

$$\begin{aligned}
 \{f_1(t_1)f_2(t_2, t_3)\}_s &= \frac{1}{3} (f_1(t_1)f_2(t_2, t_3) \\
 &\quad + f_1(t_2)f_2(t_1, t_3) + f_1(t_3)f_2(t_1, t_2)).
 \end{aligned} \tag{17}$$

Poisson Process

Poisson process is a special case of a point process, whose increments $dN(t)$ defined on disjoint time intervals dt are independent. The nonhomogeneous Poisson process is completely characterized by its first-order product density:

$$f_1(t) = v(t), \tag{18}$$

(16) which is the *intensity* of the Poisson process.

Higher-order correlation functions are equal to zero:

$$g_n(t_1, \dots, t_n) = 0 \quad (19)$$

for $n > 1$.

Due to the independence of events, Eq. 2 becomes

$$f_n(t_1, \dots, t_n) = \prod_{i=1}^n v(t_i). \quad (20)$$

Substitution of Eq. 20 into Eq. 14 and into Eq. 15 yields, respectively (Snyder and Miller 1991),

$$\pi_n(t_1, \dots, t_n) = \prod_{i=1}^n v(t_i) \exp\left(-\int_0^t v(\tau) d\tau\right), \quad (21)$$

$$\Pr\{N(t) = n\} = \frac{1}{n!} \left(\int_0^t v(\tau) d\tau\right)^n \exp\left(-\int_0^t v(\tau) d\tau\right). \quad (22)$$

For a homogeneous Poisson process ($v(t) = v = \text{const.}$), the following expressions are obtained:

$$f_n(t_1, \dots, t_n) = v^n, \quad (23)$$

$$\pi_n(t_1, \dots, t_n) = v^n \exp(-vt), \quad (24)$$

$$\Pr\{N(t) = n\} = \frac{(vt)^n}{n!} \exp(-vt). \quad (25)$$

Renewal Processes

The renewal process can be defined as a sequence of random time points $t_1, t_2, \dots, t_n$ on the positive real line, such that

$$t_i - t_{i-1} = T_i, \quad i = 2, 3, \dots, t_1 = T_1, \quad (26)$$

where the time intervals $\{T_i, i = 2, 3, \dots\}$ between the successive points, called *inter-arrival times*, are the positive, independent, and identically distributed random variables. The point process is called an *ordinary renewal process* if the time T_1 measured from the origin to

the first event has the same distribution as other time intervals T_i . This means that the time origin is placed at the instant of 0th, or initial, event which is not counted. If T_1 has another distribution than other time intervals T_i , the point process is called a *general* or *delayed renewal process*. In that case the time origin is placed arbitrarily.

An ordinary renewal process can be defined equivalently as the sequence of positive, independent, and identically distributed random variables $\{T_i, i = 1, 2, \dots\}$.

Consider an interval $[0, t]$ of the time axis. An *ordinary renewal density* $h_o(t)$ (Cox 1962; Cox and Isham 1980) represents the probability that a random point (not necessarily the first) occurs in $[t, t + dt]$, given that a random point occurs at the origin. A *modified renewal density* $h_m(t)$ (Cox 1962) represents the probability that a random point (not necessarily the first) occurs in $[t, t + dt]$, with arbitrarily chosen time origin. A modified renewal density is the first-order product density of the renewal point process:

$$h_m(t)dt = \Pr\{dN(t) = 1\} = f_1(t)dt. \quad (27)$$

If this probability is irrespective of the position of the interval $[t, t + dt]$ on the time axis, the renewal process is stationary.

Product densities of higher degrees of a renewal process appear to split into a product form or get factorized (Srinivasan 1974):

$$\begin{aligned} f_n(t_1, \dots, t_n) dt_1 \dots dt_n &= E[dN(t_1) \dots dN(t_n)] \\ &= h_m(t_1) h_o(t_2 - t_1) h_o(t_3 - t_2) \dots \\ &\quad h_o(t_n - t_{n-1}) dt_1 dt_2 \dots dt_n, \\ &\quad (t_1 < t_2 < \dots < t_n), \end{aligned} \quad (28)$$

hence

$$f_n(t_1, \dots, t_n) = h_m(t_1) h_o(t_2 - t_1) h_o(t_3 - t_2) \dots h_o(t_n - t_{n-1}) \quad (t_1 < t_2 < \dots < t_n). \quad (29)$$

Let the probability density of the random variable X_1 be denoted as $g_1(t)$ and the probability density of each of the variables $\{T_i, i = 2, 3, \dots\}$ as $g(t)$. It can be shown that the renewal densities $h_m(t)$ and $h_o(t)$ satisfy, respectively,

inhomogeneous Volterra integral equations of the second kind, called *renewal equations*. These equations are derived (Srinivasan 1974) by considering the fact that the occurrence of the point in $[t, t + dt]$ is due to two mutually exclusive events: either it is the first point or it is the subsequent point. If it is the first point, the probability of its occurrence is just $g_1(t)dt$ (in the case of a delayed renewal process) or $g(t)dt$ (in the case of an ordinary renewal process). If it is the subsequent point, the preceding one has occurred at an arbitrary $t - u$, $u \in [0, t]$, u being the time interval between those two points. This leads to the following integral equations:

$$h_m(t) = g_1(t) + \int_0^t h_m(t-u)g(u)du, \quad (30)$$

$$h_o(t) = g(t) + \int_0^t h_o(t-u)g(u)du. \quad (31)$$

The renewal densities can be evaluated by taking the Laplace transforms of the equations Eqs. 30 and 31, which finally yields (Cox 1962; Cox and Isham 1980)

$$h_m(t) = \mathcal{L}^{-1} \left\{ \frac{g_1^*(s)}{1 - g^*(s)} \right\}, \quad (32)$$

$$h_o(t) = \mathcal{L}^{-1} \left\{ \frac{g^*(s)}{1 - g^*(s)} \right\}, \quad (33)$$

where $\mathcal{L}^{-1} \{ \dots \}$ denotes an inverse Laplace transform.

A class of the renewal processes which is important in applications are Erlang processes, where the time intervals between events have gamma (or Pearson type III) probability distribution with the density function

$$g(t) = v^k t^{k-1} \exp(-vt) / (k-1)!, \quad t > 0, \quad (34)$$

where $k = 1, 2, 3, \dots$. A homogeneous Poisson process is a special case of such a process, specified by letting $k = 1$, in which case the time intervals have the negative exponential distribution characterized by the density function:

$$g(t) = v \exp(-vt), \quad t > 0. \quad (35)$$

An important property of the gamma distribution with density function given by Eq. 34 is that it is the distribution of the sum of k independent random variables, each of whose distribution is negative exponential with parameter v . Hence, the events driven by an Erlang process with parameter k can be regarded as every k th event of the generating Poisson process with the mean arrival rate v .

The renewal densities of the Erlang process are

$$h_o(t) = \frac{v}{2} (1 - \exp(-2vt)), \quad k = 2, \quad (36)$$

$$h_o(t) = \frac{v}{3} \left[1 - \left(\sqrt{3} \sin \frac{\sqrt{3}}{2} vt + \cos \frac{\sqrt{3}}{2} vt \right) \exp \left(-\frac{3}{2} vt \right) \right], \quad k = 3, \quad (37)$$

$$h_o(t) = \frac{v}{4} [1 - 2 \sin(vt) \exp(-vt) - \exp(-2vt)], \quad k = 4. \quad (38)$$

It is interesting to note that, although the Erlang events are every k th Poisson events, the renewal densities, which are the mean arrival rates of Erlang events, only asymptotically (as $t \rightarrow \infty$) tend to v/k .

Random Pulse Trains Driven by Different Stochastic Point Processes

Random Trains of Overlapping Pulses: Filtered Stochastic Point Processes

General Case

A filtered stochastic point process $\{X(t), t \in [0, t]\}$ is defined as

$$X(t) = \sum_{i=1}^{N(t)} s(t, t_i \mathbf{P}_i), \quad (39)$$

where $\{N(t), t \in [0, \infty]\}$ is a general counting process and $\mathbf{P}_i$ is a vector random variable

Non-Poisson Impulse Processes, Fig. 1 Train of overlapping pulses

attributed to a random point t_i . In a general case, the random variables which are the components of the vector $\mathbf{P}_i$ do not have to be independent, they can be correlated, and they can be characterized by different probability distributions, nor have the vector random variables $\mathbf{P}_i$ attributed to different points to be mutually independent or identically distributed. The only assumption made at present is that these random variables are statistically independent of the counting process $N(t)$. The nonrandom function $s(t, t_i, \cdot)$, called the *filter function*, represents the effect at the time t of an event occurring at the random instant t_i , the event being characterized by a vector random variable $\mathbf{P}_i$. For causality reasons, it is assumed that $s(t, \tau, \mathbf{P}_i) = 0$ for $\tau > t$. Hence, the process of Eq. 39 represents the cumulative effect of a train of point events occurring at random instants t_i belonging to the interval $[0, t]$, described by a general stochastic point process. The process $X(t)$, $t \in [0, \infty]$ defined by the formula Eq. 39 can be interpreted as a random train of general pulses $F(t)$ (Fig. 1), or signals, with origins at the random times t_i ; $s(t, t_i, \mathbf{P}_i)$ being the *pulse shape function*.

After the division of the interval $[0, t]$ onto disjoint, contiguous subintervals, $X(t)$ can be written down as the Riemann–Stieltjes sum. The limit, in the mean-square sense, of the sequence of such sums, is the mean-square Riemann–Stieltjes integral with respect to the counting process $N(t)$ or the stochastic integral:

$$X(t) = \int_0^t s(t, \tau, \mathbf{P}(\tau)) dN(\tau), \quad (40)$$

where $\mathbf{P}(\tau)$ is the vector random variable assigned to the point occurring in the interval $[\tau, \tau + d\tau]$.

The expected value of the process $X(t)$ is obtained just by averaging the expression Eq. 40, which yields (Iwankiewicz 1995)

$$\begin{aligned} E[X(t)] &= \int_0^t E[s(t, \tau, \mathbf{P}(\tau))] f_1(\tau) d\tau \\ &= \int_0^t \int_{\mathcal{P}_\tau} s(t, \tau, \mathbf{p}) f_{\mathbf{P}}(\mathbf{p}, \tau) f_1(\tau) d\mathbf{p} d\tau, \quad (41) \end{aligned}$$

where $f_{\mathbf{P}}(\mathbf{p}, \tau)$ is the joint probability density of the vector random variable $\mathbf{P}(\tau)$, which may be time variant, and $\mathcal{P}_\tau$ is the sample space of this vector random variable.

Subsequent moments of the process $X(t)$ are evaluated by averaging of the pertinent multifold integrals obtained based on Eq. 40.

For example, the second-order moment (the mean square) is obtained as

$$\begin{aligned} E[X^2(t)] &= \int_0^t \int_0^t E[s(t, \tau_1, \mathbf{P}(\tau_1)) s(t, \tau_2, \mathbf{P}(\tau_2))] \\ &\quad E[dN(\tau_1) dN(\tau_2)]. \quad (42) \end{aligned}$$

In order to evaluate this integral, the degeneracy property of the second-degree product density must be taken into account, which takes place within the integration domain, for $\tau_1 = \tau_2$. This yields

$$\begin{aligned}
 E[X^2(t)] &= \int_0^t E[s^2(t, \tau, \mathbf{P}_\tau)] f_1(\tau) d\tau \\
 &+ \iint_{00}^t E[s(t, \tau_1, \mathbf{P}_{\tau_1}) s(t, \tau_2, \mathbf{P}_{\tau_2})] f_2(\tau_1, \tau_2) d\tau_1 d\tau_2. \\
 E[X(t_1)X(t_2)] &= \int_0^{\min(t_1, t_2)} E[s(t_1, \tau, \mathbf{P}(\tau)) s(t_2, \tau, \mathbf{P}(\tau))] f_1(\tau) d\tau \\
 &+ \iint_{00}^{t_1 t_2} E[s(t_1, \tau_1, \mathbf{P}(\tau_1)) s(t_2, \tau_2, \mathbf{P}(\tau_2))] f_2(\tau_1, \tau_2) d\tau_1 d\tau_2.
 \end{aligned}
 \tag{43}$$

Likewise the correlation function of the process $X(t)$ is obtained as

The general expression for the n th order moment is

$$E[X^n(t)] = \underbrace{\int_0^t \cdots \int_0^t}_{n\text{-fold}} E\left[\prod_{k=1}^n s(t, \tau_k, \mathbf{P}(\tau_k))\right] E\left[\prod_{k=1}^n dN(\tau_k)\right]. \tag{45}$$

Of course, as $\tau_1 \neq \tau_2 \neq \dots \neq \tau_n$, then

$$E\left[\prod_{k=1}^n dN(\tau_k)\right] = f_n(\tau_1, \dots, \tau_n) d\tau_1 \cdots d\tau_n. \tag{46}$$

In the multidimensional integration domain, any possible equations of the arguments τ_k take place. Therefore, in order to evaluate the integral

Eq. 45, all possible degeneracies of n th degree product density $f_n(\tau_1, \dots, \tau_n)$ must be taken into account. Moreover, in general case, the integration is performed with respect to the joint probability density of n vector random variables $\mathbf{P}_k, k = 1, 2, \dots, n$.

In particular the expression for the third-order moment is obtained as

$$\begin{aligned}
 E[X^3(t)] &= \int_0^t E[s^3(t, \tau, \mathbf{P}_\tau)] f_1(\tau) d\tau \\
 &+ 3 \iint_{00}^t E[s^2(t, \tau_1, \mathbf{P}(\tau_1)) s(t, \tau_2, \mathbf{P}(\tau_2))] f_2(\tau_1, \tau_2) d\tau_1 d\tau_2 \\
 &+ \iiint_{000}^t E[s(t, \tau_1, \mathbf{P}(\tau_1)) s(t, \tau_2, \mathbf{P}(\tau_2)) s(t, \tau_3, \mathbf{P}(\tau_3))] f_3(\tau_1, \tau_2, \tau_3) d\tau_1 d\tau_2 d\tau_3.
 \end{aligned}
 \tag{47}$$

However, in general, the evaluation of the above integrals becomes cumbersome, especially in the case of higher-order moments. Then, in the case of a Poisson process, it is much easier to handle the cumulants, which can be obtained directly from the log-characteristic function, called also a cumulant-generating function. In the case of a filtered renewal process, the

recursive expressions for the moments can be obtained from the integral equations governing the characteristic function.

Filtered Renewal Process

Consider a filtered process $\{X(t), t \in [0, \infty]\}$, driven by an ordinary renewal counting process $\{X(t), t \in [0, \infty]\}$, in the form of

$$X(t) = \sum_{j=1}^{N(t)} s(t - t_j, P_j), \quad (48)$$

where the filter function is assumed to be causal, i.e., $s(\tau, P_j) = 0$ for $\tau < 0$. The random variables P_j are assumed to be independent and to have identical probability distributions characterized by the common density function $f_P(p)$. The probability distributions of the inter-arrival times are characterized by the probability distribution function $G(t)$ and by the probability density function $g(t)$.

The characteristic function $\Phi_X(\theta, t)$ of the filtered renewal process $X(t)$ defined by Eq. 48 appears to satisfy the inhomogeneous Volterra integral equation of the second kind. The following derivation is due to Takacs (1956).

The filtered process $X(t)$ given by Eq. 48 may be regarded as a sum of the first pulse occurring after first inter-arrival time T_1 and the filtered process with the origin shifted by T_1 , i.e., $X(t - T_1)$; thus,

$$X(t) = s(t - T_1, P_1) + X(t - T_1). \quad (49)$$

Suppose that $T_1 = \tau$. In view of independence of random variables P_j , the conditional characteristic function, given that the first pulse occurs at the time $T_1 = \tau$, is expressed as

$$\begin{aligned} \Phi_X(\theta, t | T_1 = \tau) &= E[\exp(i\theta X(t) | T_1 = \tau)] \\ &= E[\exp(is(t - \tau, P_1)) \exp(i\theta X(t - \tau))] \\ &= \Gamma(\theta, t - \tau) \Phi_X(\theta, t - \tau), \end{aligned} \quad (50)$$

where

$$\begin{aligned} \Gamma(\theta, t - \tau) &= E[\exp\{i\theta s(t - \tau, P)\}] \\ &= \int_{-\infty}^{\infty} \exp[i\theta s(t - \tau, p)] f_P(p) dp \end{aligned} \quad (51)$$

is the characteristic function of a single general pulse $s(t - \tau, P)$.

By unconditioning one obtains

$$\Phi_X(\theta, t) = \int_0^t \Phi_X(\theta, t - \tau) \Gamma(\theta, t - \tau) g(\tau) d\tau + C, \quad (52)$$

where the integration constant C is evaluated from the obvious condition for $\theta = 0$

$$\Phi_X(0, t) = 1 = \int_0^t g(\tau) d\tau + C, \quad (53)$$

thus $C = 1 - G(t)$.

Hence, the final result is

$$\Phi_X(\theta, t) = \int_0^t \Phi_X(\theta, t - \tau) \Gamma(\theta, t - \tau) g(\tau) d\tau + 1 - G(t). \quad (54)$$

After differentiating the Eq. 54 r times with respect to θ and after substituting $\theta = 0$, the following integral equation governing the moment $E[X^r(t)]$ is arrived at

$$E[X^r(t)] = \sum_{i=0}^r \binom{r}{i} \int_0^t \phi_{r-i}(t - \tau) E[X^i(t - \tau)] g(\tau) d\tau, \quad (55)$$

where

$$\begin{aligned} \phi_k(t - \tau) &= E[s^k(t - \tau, P)] \\ &= \int_{-\infty}^{\infty} s^k(t - \tau, p) f_P(p) dp. \end{aligned} \quad (56)$$

Taking Laplace transforms of the both sides of Eq. 55, solving the obtained algebraic equation for the transform of the r th order moment, and taking the inverse transform, one obtains the following recursive expression (Takacs 1956):

$$E[X^r(t)] = \sum_{i=0}^{r-1} \binom{r}{i} \int_0^t \phi_{r-i}(t - \tau) E[X^i(t - \tau)] h_o(\tau) d\tau, \quad (57)$$

where $h_o(\tau)$ is the ordinary renewal density.

Non-Poisson Impulse Processes, Fig. 2 Beam under a random train of moving loads

The specific formulae for the mean value function $E[X(t)]$ and the mean-square function $E[X^2(t)]$ are obtained as

$$E[X(t)] = \int_0^t \phi_1(t - \tau) h_o(\tau) d\tau, \quad (58)$$

$$E[X^2(t)] = \int_0^t \phi_2(t - \tau) h_o(\tau) d\tau + 2 \int_0^t \int_0^t \phi_1(t - \tau) \phi_1(t - u) h_o(u - \tau) h_o(\tau) du d\tau, \quad (59)$$

where

$$\phi_1(t - \tau) = E[s(t - \tau, P)], \quad (60)$$

$$\phi_2(t - \tau) = E[s^2(t - \tau, P)]. \quad (61)$$

The same result for $E[X^2(t)]$ as Eq. 59 is obtained if the expression Eq. 29 for the second-order product density for the ordinary renewal process is inserted into the general expression Eq. 43. In the integration domain $\tau_1 \in (0, t)$, $\tau_2 \in (0, t)$, it must be assumed

$$f_2(\tau_1, \tau_2) = \begin{cases} h_o(\tau_1) h_o(\tau_2 - \tau_1), & \tau_2 > \tau_1, \\ h_o(\tau_1) h_o(\tau_2 - \tau_1), & \tau_2 > \tau_1. \end{cases} \quad (62)$$

More results for the moments of the filtered renewal process (e.g., the response of a linear

dynamic system to a renewal pulse train) may be found in Iwankiewicz (1995).

Example Problem: Dynamic Response of a Bridge (Beam) to a Random Train of Moving Loads

Consider the well known in structural engineering problem of the dynamic response of a highway bridge to the moving load due to the vehicular traffic. It is known that if the bridge has a long span, the coupling of the motion of the bridge and of the vehicle as well as the inertia of the vehicle may be neglected and the vehicles may be adequately idealized by point forces. The times of occurrence of vehicles at the bridge are random, and in the simplest case, all the vehicles may be assumed to travel with the same, constant velocity. The bridge, idealized as a beam, is then subjected to a random train of moving forces with random magnitudes P_j and at a given time instant t randomly located at the beam, as shown in Fig. 2.

The equation governing the transverse motion of the beam has the form

$$EI \frac{\partial^4 w(x, t)}{\partial x^4} + c \frac{\partial w(x, t)}{\partial t} + \mu \frac{\partial^2 w(x, t)}{\partial t^2} = \sum_{j=1}^{N(t)} P_j \delta(x - v(t - t_j)). \quad (63)$$

Application of the normal mode approach

$$w(x, t) = \sum_{i=1}^n q_i(t) \phi_i(x), \quad (64)$$

Non-Poisson Impulse Processes,

Fig. 3 Different gamma probability density plots

where $\varphi_i(x)$ are the normal modes, yields the equations

$$\ddot{q}_i(t) + 2\zeta_i\omega_i\dot{q}_i(t) + \omega_i^2q_i(t) = \beta_i \sum_{j=1}^{\mathcal{N}(t)} P_j \phi_i(v(t-t_j)), \quad i = 1, 2, \dots, n \quad (65)$$

where $\phi_i(v(t-t_j)) = s(t-t_j)$ plays the role of the pulse shape.

Thus, the problem is converted into the problem of the random train of general pulses. The underlying counting process $\mathcal{N}(t)$ may be any counting process. It is known from the highway traffic engineering that the inter-arrival times between the vehicles are adequately idealized as positive random variables with a unimodal probability density function. If the inter-arrival times are independent and identically distributed, the underlying counting process is a renewal process.

For example, if the renewal process is an Erlang process, the probability density function of the inter-arrival times is

$$g(t) = \frac{v^k t^{k-1}}{(k-1)!} \exp(-vt), \quad t > 0. \quad (66)$$

Some example probability density plots are shown in Fig. 3.

Example Problem: Dynamic Response of Linear System to a Random Train of Impulses

A random train of impulses, or an impulse process excitation, $F(t)$ is shown in Fig. 4.

Vibrations of a linear oscillator under a random train of impulses are governed by

$$\ddot{Y}(t) + 2\zeta\omega\dot{Y}(t) + \omega^2Y(t) = F(t) = \sum_{i=1}^{\mathcal{N}(t)} P_i \delta(t-t_i), \quad (67)$$

where $\mathcal{N}(t)$ is a stochastic point (random counting) process, giving the random number of time points t_i in the time interval $[0, t]$, i.e., excluding the one that may occur at t . The impulse magnitudes P_i are independent random variables, identically distributed as a random variable P . The variables P_i are also statistically independent of the random times t_i or of the counting process $\mathcal{N}(t)$. The counting process may be, e.g., a Poisson or a renewal process.

From the impulse-momentum principle, it follows that

$$\dot{Y}(t_i)_+ = \dot{Y}(t_i)_- + P_i.$$

Hence, the velocity response process $\dot{Y}(t)$ changes by jumps; it is piecewise continuous.

Consequently the displacement response process $Y(t)$ is continuous, but it is only piecewise continuously differentiable.

Non-Poisson Impulse Processes,

Fig. 4 Random train of impulses

The jump change in the velocity may occur at any point; hence, the usual rules of calculus do not apply.

The usual notation of the differential equation of motion is **not mathematically meaningful**.

Stochastic counterparts of the usual differential equations are the **stochastic differential equations**:

$$dY(t) = \dot{Y}(t)dt, d\dot{Y}(t) = -2\zeta\omega\dot{Y}(t)dt - \omega^2 Y(t)dt + P(t)d\mathcal{N}(t), \quad (68)$$

where $P(t)$ is the magnitude of the impulse which occurs in the time interval $[t, t + dt)$.

Nevertheless, the response of **linear dynamical systems** may be directly analyzed in **time domain**. The explicit expression for the response to a random train of impulses, based on the **linear superposition principle**, is obtained as

$$Y(t) = \sum_{i=1}^{\mathcal{N}(t)} P_i h(t - t_i) = \int_0^t P(\tau) h(t - \tau) d\mathcal{N}(\tau), \quad (69)$$

where $h(t) = \frac{1}{\omega_d} \exp(-\zeta\omega t) \sin \omega_d t$ is the **impulse response function** and $\omega_d = \omega \sqrt{1 - \zeta^2}$. The integral with respect to the increments of the stochastic point process is the stochastic counterpart of the usual Duhamel convolution integral.

Statistical moments of the response process may be evaluated by averaging of the pertinent multifold integrals Eq. 45.

Response of Dynamic Systems to Non-Poisson Impulse Processes. State-Space Formulation

Itô's differential rule for nondiffusive, Poisson-driven Markov processes

The stochastic equations of motion of the dynamic system subjected to a Poisson impulse process excitation are

$$d\mathbf{Y}(t) = c(\mathbf{Y}(t), t)dt + b(\mathbf{Y}(t), t)P(t)d\mathcal{N}(t), \mathbf{Y}(0) = y_0. \quad (70)$$

If the excitation process is statistically independent of the initial conditions, the vector process $\mathbf{Y}(t) = [Y_1(t), Y_2(t), \dots, Y_n(t)]^T$ is a **nondiffusive, Poisson-driven, Markov process**.

If the function $V(\mathbf{Y}(t), t)$ is bounded for t and $\mathbf{Y}(t)$ finite and is once continuously differentiable with respect to all its arguments, the differential of a compound function $V(t, \mathbf{Y}(t))$ of the state variables $\mathbf{Y}(t)$ is expressed by the following **generalized Itô's differential rule** (Snyder and Miller 1991; Iwankiewicz and Nielsen 1999):

$$\begin{aligned} dV(t, \mathbf{Y}(t)) &= \frac{\partial V(t, \mathbf{Y}(t))}{\partial t} dt \\ &+ \sum_{i=1}^n \frac{\partial V(t, \mathbf{Y}(t))}{\partial Y_i} c_i(\mathbf{Y}(t), t) dt \\ &+ [V(t, \mathbf{Y}(t) + b(\mathbf{Y}(t), t, P(t))) - V(t, \mathbf{Y}(t))] d\mathcal{N}(t). \end{aligned} \quad (71)$$

Differential equations governing the response joint statistical moments $\mu_{ij}(t) = E[Y_i(t)Y_j(t)]$, $\mu_{ijk}(t) = E[Y_i(t)Y_j(t)Y_k(t)]$, $\mu_{ijkl}(t) = E[Y_i(t)Y_j(t)Y_k(t)Y_l(t)]$,

etc. are derived from this rule by assuming the function $V(t, \mathbf{Y}(t))$ in form of different products of the state variables, for example, $V(t, \mathbf{Y}(t)) = Y_i(t)Y_j(t)$, $V(t, \mathbf{Y}(t)) = Y_i(t)Y_j(t)Y_k(t)$, and $V(t, \mathbf{Y}(t)) = Y_i(t)Y_j(t)Y_k(t)Y_l(t)$.

Next, the expectation of both sides of the above differential rule must be taken and

$$E[dV(t, \mathbf{Y}(t))] = dE[V(t, \mathbf{Y}(t))].$$

The effective averaging is possible if the driving process is a Poisson process, because then the increment $dN(t) = N(t+dt) - N(t)$ is statistically independent of $V(t, \mathbf{Y}(t))$ and

$$\begin{aligned} E[V(t, \mathbf{Y}(t))dN(t)] &= E[V(t, \mathbf{Y}(t))]E[dN(t)] \\ &= E[V(t, \mathbf{Y}(t))]v(t)dt. \end{aligned}$$

For a general Poisson-driven pulse problem, the equations for the mean values, the second-, third-, and fourth-order joint central moments of the response, are obtained as

$$\dot{\mu}_i(t) = E[c_i(\mathbf{Y}(t), t)] + v(t)E[P]E[b_i(\mathbf{Y}(t), t)] \quad (72)$$

$$\begin{aligned} \dot{\kappa}_{ij}(t) &= 2 \left\{ E \left[Y_i^0 \left(c_j^0(\mathbf{Y}^0(t), t) + v(t)b_j(\mathbf{Y}(t), t)P \right) \right] \right\}_s \\ &\quad + v(t)E[P^2]E[b_i(\mathbf{Y}(t), t)b_j(\mathbf{Y}(t), t)] \end{aligned} \quad (73)$$

$$\begin{aligned} \dot{\kappa}_{ijk}(t) &= 3 \left\{ E \left[Y_i^0 Y_j^0 \left(c_k^0(\mathbf{Y}^0(t), t) + v(t)b_k(\mathbf{Y}(t), t)P \right) \right] \right\}_s \\ &\quad + 3v(t)E[P^2] \left\{ E \left[Y_i^0 b_j(\mathbf{Y}(t), t)b_k(\mathbf{Y}(t), t) \right] \right\}_s \\ &\quad + v(t)E[P^3]E[b_i(\mathbf{Y}(t), t)b_j(\mathbf{Y}(t), t)b_k(\mathbf{Y}(t), t)] \end{aligned} \quad (74)$$

$$\begin{aligned} \dot{\kappa}_{ijkl}(t) &= 4 \left\{ E \left[Y_i^0 Y_j^0 Y_k^0 \left(c_l^0(\mathbf{Y}^0(t), t) + v(t)b_l(\mathbf{Y}(t), t)P \right) \right] \right\}_s \\ &\quad + 6v(t)E[P^2] \left\{ E \left[Y_i^0 Y_j^0 b_k(\mathbf{Y}(t), t)b_l(\mathbf{Y}(t), t) \right] \right\}_s \\ &\quad + 4v(t)E[P^3] \left\{ E \left[Y_i^0 b_j(\mathbf{Y}(t), t)b_k(\mathbf{Y}(t), t)b_l(\mathbf{Y}(t), t) \right] \right\}_s \\ &\quad + v(t)E[P^4]E[b_i(\mathbf{Y}(t), t)b_j(\mathbf{Y}(t), t)b_k(\mathbf{Y}(t), t)b_l(\mathbf{Y}(t), t)] \end{aligned} \quad (75)$$

N

where $Y_i^0(t) = Y_i(t) - \mu_i(t)$ and $c_j^0(\mathbf{Y}^0(t), t) = c_j(\mathbf{Y}(t), t) - E[c_j(\mathbf{Y}(t), t)]$ denote the components of the zero-mean (centralized) state vector and drift vector, respectively; $E[P^r]$ denotes the r th moment of the random variable P , i.e., $E[P^r] = \int_{\mathbf{P}} p^r f_P(p) dp$; and $\{\dots\}_s$ denotes the

Stratonovich symmetrizing operation, e.g.,

$$\{Y_i Y_j c_k\}_s = \frac{1}{3} (Y_i Y_j c_k + Y_i Y_k c_j + Y_j Y_k c_i). \quad (76)$$

Equations for response moments of a linear system form always a closed set and can be directly solved numerically. Equations for response moments of a nonlinear system with polynomial nonlinearity form an infinite hierarchy.

Then special closure approximations (truncation procedures) must be used. For other types of nonlinearity, the equations involve unknown expectations of nonlinear functions of state variables, and some tentative forms of the joint probability density must be used (Iwankiewicz et al. 1990).

Conversion of Non-Markov Impulse Problems to Markov Ones

Non-Markov Nature of the State Vector of the Dynamic System

A renewal impulse process is

$$F(t) = \sum_{i, R=1}^{R(t)} P_{i, R} \delta(t - t_{i, R}) \quad (77)$$

Non-Poisson Impulse Processes, Fig. 5 Train of Erlang impulses. $\times$: Poisson-driven points, $\circ$: Erlang-driven points

where the occurrence times $t_{i,R}$ of impulses are driven by a renewal process. $R(t)$ and $P_{i,R}$ are statistically independent and identically distributed random magnitudes of the impulses.

The stochastic equations of motion in a general case of a nonlinear oscillator and a parametric excitation are

$$\begin{aligned} dY(t) &= \dot{Y}(t)dt, d\dot{Y}(t) \\ &= f(Y(t), \dot{Y}(t))dt + b(Y(t), \dot{Y}(t))P(t)dR(t), \end{aligned} \quad (78)$$

where $f(Y(t), \dot{Y}(t))$ is a nonlinear function of the instantaneous values of $Y(t)$ and $\dot{Y}(t)$ which represents all restoring force together with damping terms of the equation of motion and $b(Y(t), \dot{Y}(t))$ is the parametric excitation term. As the increments $dR(t)$ of the renewal counting process $R(t)$ are not independent, the state vector $\mathbf{Y}(t) = [Y(t), \dot{Y}(t)]^T$ is **not a Markov process**.

Augmentation of a State Vector by Additional Variables

A basic idea of conversion of a non-Markov impulse problem to a Markov one is to replace the original train of impulses by an equivalent one for which the response process becomes a Markov process.

If the impulse process is driven by an Erlang renewal process, the following exact replacement is valid with probability 1 (Iwankiewicz and Nielsen 1999):

$$\sum_{i,R=1}^{R(t)} P_{i,R} \delta(t - t_{i,R}) = \sum_{i=1}^{N(t)} \rho(N(t_i)) P_i \delta(t - t_i). \quad (79)$$

Based on the fact that the events of the Erlang renewal process are every second, or every third, or every fourth, etc. Poisson events, a zero-memory transformation $\rho(N(t))$ of the homogeneous Poisson process $N(t)$ is introduced which assumes values $\rho(N(t_i)) = 1$ for every k th Poisson event and $\rho(N(t_i)) = 0$ for all other Poisson events. The sample paths of $\rho(N(t))$ are assumed to be left continuous with right limits. The arrival times t_i are driven by a homogeneous Poisson process $N(t)$ with a mean arrival rate ν , and the impulse magnitudes P_i are compounded with $\rho(N(t_i))$. Thus, the actual impulse process is obtained by selecting, with the aid of an auxiliary stochastic variable $p(N(t))$, every k th impulse from the train driven by a Poisson process $N(t)$. The replacement Eq. 79 is illustrated in Fig. 5, where the dashed-line spikes represent these of the impulses driven by $N(t)$, whose magnitudes are multiplied by $\rho(N(t_i)) = 0$, hence are excluded, and the solid-line spikes represent the remaining $N(t)$ -driven impulses, whose magnitudes are multiplied by $\rho(N(t_i)) = 1$; hence, these are the impulses driven by the underlying Erlang renewal process $R(t)$.

Consequently the increments of the Erlang renewal process can be expressed in terms of the Poisson counting process:

$$dR(t) = \rho(N(t))dN(t). \quad (80)$$

The transformation $\rho(N(t))$ is expressed in terms of the auxiliary variables $C_j(t)$ and $S_j(t)$ (Iwankiewicz and Nielsen 1999):

$$\rho(N(t)) = \rho(C_j(N(t)), S_j(N(t))) \quad (81)$$

where

$$\begin{aligned} C_j(N(t)) &= \cos\left(\frac{j\pi N(t)}{k}\right), \quad S_j(N(t)) \\ &= \sin\left(\frac{j\pi N(t)}{k}\right) \end{aligned} \quad (82)$$

hence

$$dR(t) = \rho(C_j(N(t)), S_j(N(t))) dN(t). \quad (83)$$

For example, if $k = 2$, $k = 3$, and $k = 4$, the required transformations of the Poisson counting process $N(t)$, such that $\rho(N(t)) = 1$ for every second, third, and fourth Poisson event and $\rho(N(t)) = 0$ for all other Poisson events, are, respectively,

$$\begin{aligned} \rho(N(t)) &= \frac{1}{2} (1 - \cos(\pi N(t))) \\ &= \frac{1}{2} (1 - (-1)^{N(t)}), \end{aligned} \quad (84)$$

$$\rho(N(t)) = \frac{1}{3} \left(1 - \sqrt{3} \sin\left(\frac{2}{3}\pi N(t)\right) - \cos\left(\frac{2}{3}\pi N(t)\right) \right), \quad (85)$$

$$\rho(N(t)) = \frac{1}{4} \left(1 - 2 \sin\left(\frac{1}{2}\pi N(t)\right) - \cos(\pi N(t)) \right). \quad (86)$$

For all auxiliary variables $C_j(t)$ and $S_j(t)$, the stochastic differential equations are written down, which are all driven by the Poisson process $N(t)$.

It should be noted that as the increment $dN(t)$ is independent of $N(t)$, then $dN(t)$ is independent of $\rho(N(t))$.

The original state vector $\mathbf{Y}(t) = [Y(t), \dot{Y}(t)]^T$ is augmented by the auxiliary variables $C_j(t)$ and $S_j(t)$ to make up a vector $\mathbf{Z}(t)$:

$$\begin{aligned} d\mathbf{Z}(t) &= \mathbf{c}(\mathbf{Z}(t), t) dt \\ &+ \mathbf{b}(\mathbf{Z}(t), t,) P(t) dN(t), \quad \mathbf{Z}(0) = \mathbf{z}_0. \end{aligned} \quad (87)$$

The augmented state vector $\mathbf{Z}(t)$ is driven by a Poisson process; hence, it is a **nondiffusive (Poisson-driven) Markov process**. Equations for

moments may be derived from the Itô's differential rule for Poisson-driven Markov processes.

Now the renewal, impulse process excitation is considered where the inter-arrival times T_a are the sum of two independent, negative exponential distributed variables T_r and T_d , with probability density functions given, respectively, by (for $t > 0$)

$$\begin{aligned} g_{T_r}(t) &= v \exp(-vt), \quad g_{T_d}(t) \\ &= \mu \exp(-\mu t). \end{aligned} \quad (88)$$

The following replacement holds with probability 1 for the renewal driven train of impulses (Iwankiewicz 2003):

$$\sum_{i,R=1}^{R(t)} P_{i,R} \delta(t - t_{i,R}) = \sum_{i=1}^{N_\mu(t)} Z(t_i) P_i \delta(t - t_i), \quad (89)$$

where the arrival times $t_{i,R}$ are driven by the underlying renewal process $R(t)$, the arrival times t_i are driven by a homogeneous Poisson process $N_\mu(t)$ with a mean arrival rate μ , and $Z(t_i)$ is a value at t_{i-} of the zero-one auxiliary stochastic jump process $Z(t)$ governed by (Iwankiewicz 2002)

$$dZ(t) = (1 - Z) dN_v(t) - Z dN_\mu(t). \quad (90)$$

The processes $N_v(t)$ and $N_\mu(t)$ are independent Poisson processes, with parameters v and μ , respectively, and $dN_v(t)$ and $dN_\mu(t)$ are the increments during the infinitesimal time interval $[t, t + dt)$. The process $Z(t)$ is zero-one valued, and $dZ(t) = Z(t + dt) - Z(t)$ denotes the jump increment, which may be the jump from 0 to 1, i.e., $dZ(t) = 1$, when $Z(t) = Z(t_-) = 0$ and $dN_v(t) = 1$, or the jump from 1 to 0, i.e., $dZ(t) = -1$, when $Z(t) = Z(t_-) = 1$ and $dN_\mu(t) = 1$. The sample paths of $N(t)$ and of $Z(t)$ are assumed to be left continuous with right limits. Thus, the actual impulse process is obtained by selecting, with the aid of an auxiliary stochastic variable $Z(t)$, some impulses from the train driven by a Poisson process $N_\mu(t)$. The replacement Eq. 89 is illustrated in Fig. 6, where the dashed-line spikes represent these of

Non-Poisson Impulse Processes, Fig. 6

Train of impulses expressed in terms of the jump process $Z(t)$ driven by two Poisson processes, $\times$: N_μ -driven points, $\circ$: N_ν -driven points

the impulses driven by $N_\mu(t)$, whose magnitudes are multiplied by $Z(t_i) = 0$, hence are excluded, and the solid-line spikes represent the remaining $N_\mu(t)$ -driven impulses, whose magnitudes are multiplied by $Z(t_i) = Z(t_{i-}) = 1$; hence, these are the impulses driven by the underlying counting process $R(t)$. The inter-arrival time between the solid-line spikes (actual impulses) is exactly equal to the inter-arrival time $T_a = T_r + T_d$, as defined above. The replacement implies the equivalence of the increments $dR(t) = Z(t) dN_\mu(t)$, which holds with probability 1.

The augmented state vector $\mathbf{Z}(t) = [Y(t), \dot{Y}(t), Z(t)]^T = [Z_1(t), Z_2(t), Z_3(t)]^T$ is governed by stochastic equations:

$$\begin{aligned} dZ_1 &= Z_2 dt, \\ dZ_2 &= f(Z_1, Z_2) dt + b(Z_1, Z_2) P(t) Z_3 dN_\mu(t), \\ dZ_3 &= (1 - Z_3) dN_\nu(t) - Z_3 dN_\mu(t). \end{aligned} \quad (91)$$

The state vector $\mathbf{Z}(t) = [Z_1(t), Z_2(t), Z_3(t)]^T$ is driven by two independent Poisson processes, and hence, it is a **nondiffusive Markov process**. Equations for moments may be derived from the generalized Itô's differential rule for Poisson-driven Markov processes.

Augmentation of a State Vector by Auxiliary Markov States

General Integro-differential Equations for the Joint Probability Density of the State Vector As the explicitly introduced, pure-jump stochastic processes $\rho(N(t))$ and $Z(t)$ are Poisson driven, they are characterized by negative exponential distributed phases, hence by a chain of

Markov states. Consequently the original state variables and the states of the auxiliary pure-jump stochastic process are jointly Markovian. The jumps have to be defined in such a way that the actual impulse (i.e., the jump in the velocity response $Z_2(t)$) only occurs if there is a jump between some particular Markov states.

The problem is characterized by the set of joint probability density – discrete distribution functions $q_j(z_1, z_2, t)$ of the response state variables – the displacement $Z_1(t)$ and the velocity $Z_2(t)$, and the m states $S(t)$ of a pertinent Markov chain, defined as

$$\begin{aligned} q_j(z_1, z_2, t) dz_1 dz_2 &= \Pr \{ Z_1(t) \in (z_1, z_1 + dz_1) \\ &\wedge Z_2(t) \in (z_2, z_2 + dz_2) \wedge S(t) = j \}, \end{aligned} \quad (92)$$

where $j = 1, 2, \dots, m$. The fundamental equation for such a continuous-jump Markov process is the general forward integrodifferential Chapman–Kolmogorov equation (Gardiner 1985; Iwankiewicz and Nielsen 1999):

$$\begin{aligned} \frac{\partial}{\partial t} q_j(\mathbf{z}, t) &= - \sum_{r=1}^2 \frac{\partial}{\partial z_r} [c_r(\mathbf{z}, t) q_j(\mathbf{z}, t)] \\ &+ \sum_{i=1}^m \int_{-\infty}^{\infty} [J_{\{z\}}(\mathbf{z}, j | \mathbf{x}, i, t) q_i(\mathbf{x}, t) \\ &- J_{\{z\}}(\mathbf{x}, i | \mathbf{z}, j, t) q_j(\mathbf{z}, t)] d\mathbf{x} \end{aligned} \quad (93)$$

where in the present problem $\mathbf{q}(\mathbf{z}, t) = [q_1(\mathbf{z}, t), q_2(\mathbf{z}, t), \dots, q_m(\mathbf{z}, t)]$, $c_r(\mathbf{z}, t)$ are the drift terms of the equation of motion written down in the state space form, i.e., $c_1(\mathbf{z}, t) = z_2$, $c_2(\mathbf{z}, t) = f(\mathbf{z}, t)$, $j = 1, 2, \dots, m$ and $J_{\{z\}}(z_1, z_2, j | x_1, x_2, i, t) = J_{\{z\}}(\mathbf{z}, j | \mathbf{x}, i, t)$ is the **jump probability intensity function** defined as

$$J_{\{Z\}}(z, j | x, i, t) = \lim_{\Delta t \rightarrow 0} \frac{\Pr\{Z_1(t + \Delta t) = z_1, Z_2(t + \Delta t) = z_2, S(t + \Delta t) = j | Z_1(t) = x_1, Z_2(t) = x_2, S(t) = i\}}{\Delta t} \quad (94)$$

which is determined from the pertinent chain of Markov states as follows. When $i = j$, the Markov chain remains in the same state, and no actual impulse occurs; hence, both the displacement and the velocity state variables are continuous. The nonzero jump probability intensity functions are only defined for $i \neq j$, such that there is a transition in a Markov chain (jump in the auxiliary process). Only some of those transitions are associated with the occurrence of the actual impulse, or the jump in the velocity process $Z_2(t)$. Hence, if there is a transition from $S(t) = i$ to $S(t + \Delta t) = j$, but no actual impulse occurs (no jump in the velocity process), the jump probability intensity function is

$$J_{\{Z\}}(z_1, z_2, j | x_1, x_2, i, t) = \pi(j|i) \delta(z_1 - x_1) \delta(z_2 - x_2), \quad (95)$$

where

$$\pi(j|i) = \frac{\Pr\{S(t + \Delta t) = j | S(t) = i\}}{\Delta t} \quad (96)$$

is determined from the pertinent chain of Markov states. If the transition from $S(t) = i$ to $S(t + \Delta t) = j$ is associated with the actual impulse (the jump in the velocity process $Z_2(t)$), the jump probability intensity function is expressed as

$$J_{\{Z\}}(z_1, z_2, j | x_1, x_2, i, t) = \pi(j|i) \delta(z_1 - x_1) \int_{\mathbf{P}} \delta(z_2 - (x_2 + b(z_1, z_2)p)) f_P(p) dp \quad (97)$$

where $\mathbf{P}$ denotes the sample space and $f_P(p)$ the probability density function of the random impulse magnitude P .

Summation of the joint probability density-distribution functions $q_Z(z_1, z_2, j, t)$ over all Markov states yields the joint probability density of the original state variables:

$$q_Z(z_1, z_2, t) = \sum_{j=1}^m q_j(z_1, z_2, t). \quad (98)$$

Detailed Integrodifferential Equations for the Joint Probability Density of the State Vector for Renewal Impulse Process Driven by Two Independent Poisson Processes The jump process $Z(t)$ driven by two independent Poisson processes Eq. 90 is tantamount to a two-state Markov chain $S(t)$, such that $S(t) = 1$ when $Z(t) = 0$ and $S(t) = 2$ when $Z(t) = 1$ (Figs. 6 and 7).

If the excitation is multiplicative to the displacement process, z_1 , i.e., $b(Z_1, Z_2) = b(Z_1)$, or if it is external (additive), i.e., $b(Z_1, Z_2) = \text{const.} = b$, then when there is an impulse of magnitude p , according to the equation of motion, there is a jump in the velocity by $b(z_1)p$, i.e., a jump from x_2 to $z_2 = x_2 + b(z_1)p$.

The jump probability intensity function $J_Z(z_1, z_2, j | x_1, x_2, i, t)$ determined with the aid of the Markov chain shown in Fig. 7 equals (Iwankiewicz 2008)

$$J_Z(z_1, z_2, j | x_1, x_2, i, t) = \begin{cases} 0, & j = i, \\ \mu \delta(z_1 - x_1) \int_{\mathbf{P}} \delta(z_2 - (x_2 + b(z_1)p)) f_P(p) dp, & j = 1, i = 2, \\ v \delta(z_1 - x_1) \delta(z_2 - x_2), & j = 2, i = 1, \end{cases} \quad (99)$$

Non-Poisson Impulse Processes, Fig. 7 Markov chain for a two-state jump process driven by two independent Poisson processes

where $f_P(p)$ is the probability density function of the random impulse magnitude and P denotes the sample space of the impulse magnitude.

The explicit equations for $j = 1$ and $j = 2$ are obtained after the insertion of the jump probability intensity function Eq. 99 into Eq. 93 and integration with respect to x_1, x_2 , respectively, as (Iwankiewicz 2008)

$$\begin{aligned} \frac{\partial}{\partial t} q_1(z_1, z_2, t) = & - \sum_{r=1}^2 \frac{\partial}{\partial z_r} [c_r(z_1, z_2, t) q_1(z_1, z_2, t)] \\ & + \mu \int_P q_2(z_1, z_2 - b(z_1)p, t) f_P(p) dp - \nu q_1(z_1, z_2, t) \end{aligned} \quad (100)$$

$$\begin{aligned} \frac{\partial}{\partial t} q_2(z_1, z_2, t) = & - \sum_{r=1}^2 \frac{\partial}{\partial z_r} [c_r(z_1, z_2, t) q_2(z_1, z_2, t)] \\ & + \nu q_1(z_1, z_2, t) - \mu q_2(z_1, z_2, t). \end{aligned} \quad (101)$$

At the initial time instant $t = 0$, the continuous processes $Z_1(t) = Y(t)$, $Z_2(t) = Y(t)$ are statistically independent of the jump process, or of the Markov states. It may be assumed that the jump process starts with probability 1 from the first (“off”) state, i.e., $\Pr\{S(0) = 1\} = P_1(0) = 1$ and $\Pr\{S(0) = 2\} = P_2(0) = 0$. Consequently the random initial conditions are written as

$$\begin{aligned} q_Z(z_1, z_2, 1, 0) &= q_1(z_1, z_2, 0) = p(z_1, z_2) \cdot P_1(0) = p(z_1, z_2) \cdot 1 = p(z_1, z_2) \\ q_Z(z_1, z_2, 2, 0) &= q_2(z_1, z_2, 0) = p(z_1, z_2) \cdot P_2(0) = p(z_1, z_2) \cdot 0 = 0, \end{aligned} \quad (102)$$

where $p(z_1, z_2)$ is the joint probability density of $Z_1(0) = Y(0)$, $Z_2(0) = \dot{Y}(0)$.

If the system starts from rest, i.e., $Z_1(0) = Y(0) = 0$, $Z_2(0) = \dot{Y}(0) = 0$, then

$$\begin{aligned} q_Z(z_1, z_2, 1, 0) &= q_1(z_1, z_2, 0) = \delta(z_1) \delta(z_2) P_1(0) = \delta(z_1) \delta(z_2) \cdot 1 = \delta(z_1) \delta(z_2) \\ q_Z(z_1, z_2, 2, 0) &= q_2(z_1, z_2, 0) = \delta(z_1) \delta(z_2) P_2(0) = \delta(z_1) \delta(z_2) \cdot 0 = 0. \end{aligned} \quad (103)$$

Detailed Integrodifferential Equations for the Joint Probability Density of the State Vector for Renewal Impulse Process Driven by an Erlang Renewal Process The jump process $\rho(N(t))$ is tantamount to a k -state Markov chain $S(t)$ shown in Fig. 8.

In this model, the actual impulse, and hence the jump in the velocity variable, occurs when the jump is from the state k to 1 (cf. Fig. 5). All other jumps in the auxiliary process occur from $j-1$ to j , for $j = 2, \dots, k$, but there are no corresponding impulses.

The jump probability intensity function is expressed as (Iwankiewicz 2006)

$$\begin{aligned} J_Z(z_1, z_2, j | x_1, x_2, i, t) &= \begin{cases} \nu \delta(z_1 - x_1) \int_P \delta(z_2 - (x_2 + b(z_1)p)) f_P(p) dp, & j = 1, i = k. \\ \nu \delta(z_1 - x_1) \delta(z_2 - x_2), & j = 2, 3, \dots, k, i = j - 1 \end{cases} \end{aligned} \quad (104)$$

Non-Poisson Impulse Processes, Fig. 8 Markov chain for a jump process driven by an Erlang renewal process

The governing equations for $j = 1, 2, \dots, k$ are obtained after the insertion of the jump probability intensity function Eq. 104 into Eq. 93 and integration, as (Iwankiewicz 2006)

$$\begin{aligned}
 \frac{\partial}{\partial t} q_1(z_1, z_2, t) &= - \sum_{r=1}^n \frac{\partial}{\partial z_r} [c_r(z_1, z_2, t) q_1(z_1, z_2, t)] \\
 &\quad + v \int_{\mathbf{P}} q_k(z_1, z_2 - b(z_1)p, t) f_P(p) dp \\
 &\quad - v q_1(z_1, z_2, t) \\
 &\quad \vdots \\
 \frac{\partial}{\partial t} q_j(z_1, z_2, t) &= - \sum_{r=1}^n \frac{\partial}{\partial z_r} [c_r(z_1, z_2, t) q_j(z_1, z_2, t)] \\
 &\quad + v q_{j-1}(z_1, z_2, t) - v q_j(z_1, z_2, t), \\
 j &= 2, \dots, k.
 \end{aligned} \tag{105}$$

Generating Equation for Moments

General Equation The original state vector of the dynamic system $\mathbf{Z}(t)$ is not a Markov process,

but the original state variables together with the states of the auxiliary jump process are jointly Markovian. Therefore, the generating equation for moments must be derived for the expectations:

$$E_j[V(\mathbf{Z}(t), t)] = \int_{-\infty}^{\infty} V(\mathbf{z}(t), t) q_j(\mathbf{z}, t) d\mathbf{z}, \quad j = 1, 2, \dots, m. \tag{106}$$

$$\begin{aligned}
 \frac{d}{dt} E_j[V(\mathbf{Z}(t), t)] &= \frac{\partial}{\partial t} \int_{-\infty}^{\infty} V(\mathbf{z}(t), t) q_j(\mathbf{z}, t) d\mathbf{z} \\
 &= E_j \left[\frac{\partial}{\partial t} V(\mathbf{Z}(t), t) \right] + \int_{-\infty}^{\infty} V(\mathbf{z}(t), t) \mathcal{K}_j[q(\mathbf{z}, t)] d\mathbf{z},
 \end{aligned} \tag{107}$$

where $\mathcal{K}_j[\dots]$ is the forward integrodifferential Chapman–Kolmogorov operator (Gardiner 1985; Iwankiewicz and Nielsen 1999):

$$\begin{aligned}
 \mathcal{K}_j[q(\mathbf{z}, t)] &= - \sum_{r=1}^2 \frac{\partial}{\partial z_r} [c_r(\mathbf{z}, t) q_j(\mathbf{z}, t)] \\
 &\quad + \sum_{i=1}^m \int_{-\infty}^{\infty} [J_{\{\mathbf{Z}\}}(\mathbf{z}, j | \mathbf{x}, i, t) q_i(\mathbf{x}, t) \\
 &\quad - J_{\{\mathbf{Z}\}}(\mathbf{x}, j | \mathbf{z}, j, t) q_j(\mathbf{z}, t)] d\mathbf{x}.
 \end{aligned} \tag{108}$$

After the integration by parts of the last term and some rearrangements, the **generating equation for moments** is arrived at (Iwankiewicz 2014)

$$\begin{aligned}
 \frac{d}{dt} E_j[V(\mathbf{Z}(t), t)] &= E_j \left[\frac{\partial}{\partial t} V(\mathbf{Z}(t), t) \right] + \sum_{r=1}^2 E_j \left[\frac{\partial V(\mathbf{Z}(t), t)}{\partial z_r} c_r(\mathbf{Z}(t), t) \right] + \\
 &\quad \sum_{i=1}^m \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} [V(\mathbf{y}(t), t) J_{\{\mathbf{Z}\}}(\mathbf{y}, j | \mathbf{z}, i, t) q_i(\mathbf{z}, t) - V(\mathbf{z}(t), t) J_{\{\mathbf{Z}\}}(\mathbf{y}, i | \mathbf{z}, j, t) q_j(\mathbf{z}, t)] d\mathbf{y} d\mathbf{z}, \\
 j &= 1, 2, \dots, m.
 \end{aligned} \tag{109}$$

As the usual-sense marginal joint probability density function $q(\mathbf{z}, t)$ of the state variables is obtained by summation, so is the usual-sense expectation:

$$\begin{aligned} q(\mathbf{z}, t) &= \sum_{j=1}^m q_j(\mathbf{z}, t), \Rightarrow E[V(\mathbf{Z}(t), t)] \\ &= \sum_{j=1}^m E_j[V(\mathbf{Z}(t), t)]. \end{aligned} \quad (110)$$

Detailed Equations for the Renewal Impulse Process Driven by Two Poisson Processes The insertion of the jump probability intensity function Eq. 99 into the generating equation for moments Eq. 109 followed by the integration with respect to y yields the problem-specific generating equations for moments (Iwankiewicz 2014):

$$\begin{aligned} \frac{d}{dt} E_1[V(\mathbf{Z}(t), t)] &= E_1 \left[\frac{\partial}{\partial t} V(\mathbf{Z}(t), t) \right] + \sum_{r=1}^2 E_1 \left[\frac{\partial V(\mathbf{Z}(t), t)}{\partial Z_r} c_r(\mathbf{Z}(t), t) \right] \\ &\quad + \mu E_2 \left[\int_{\mathbf{p}} V(\mathbf{Z}(t) + \mathbf{b}(\mathbf{Z})\mathbf{p}, t) f_p(p) dp \right] - v E_1[V(\mathbf{Z}(t), t)], \\ \frac{d}{dt} E_2[V(\mathbf{Z}(t), t)] &= E_2 \left[\frac{\partial}{\partial t} V(\mathbf{Z}(t), t) \right] + \sum_{r=1}^2 E_2 \left[\frac{\partial V(\mathbf{Z}(t), t)}{\partial Z_r} c_r(\mathbf{Z}(t), t) \right] \\ &\quad + v E_1[V(\mathbf{Z}(t), t)] - \mu E_2[V(\mathbf{Z}(t), t)], \end{aligned} \quad (111)$$

where $\mathbf{b}(\mathbf{Z}) = [0, b(Z_1, Z_2)]^T$. As a result of integration with respect to $\mathbf{z}$, the Markov state probabilities may appear

$$\int_{-\infty}^{\infty} q_j(\mathbf{z}, t) d\mathbf{z} = \mathcal{P}_j(t) = \Pr\{S(t) = j\}. \quad (112)$$

Differential equations governing the time evolution of Markov states probabilities $\mathcal{P}_j(t)$ are derived from the general expression for m -state Markov chain:

$$\mathcal{P}_j(t + \Delta t) = \sum_{i=1}^m \mathcal{P}_{ji}(\Delta t) \mathcal{P}_i(t), \quad j = 1, 2, \dots, m. \quad (113)$$

Detailed Equations for the Impulse Process Driven an Erlang Renewal Process The insertion of the jump probability intensity function Eq. 104 into the generating equation for moments Eq. 109 followed by the integration with respect to y yields the problem-specific generating equations for moments (Iwankiewicz 2014):

$$\begin{aligned} \frac{d}{dt} E_1[V(\mathbf{Z}(t), t)] &= E_1 \left[\frac{\partial}{\partial t} V(\mathbf{Z}(t), t) \right] + \sum_{r=1}^2 E_1 \left[\frac{\partial V(\mathbf{Z}(t), t)}{\partial Z_r} c_r(\mathbf{Z}(t), t) \right] \\ &\quad + v E_k \left[\int_{\mathbf{p}} V(\mathbf{Z}(t) + \mathbf{b}(\mathbf{Z})\mathbf{p}, t) f_p(p) dp \right] - v E_1[V(\mathbf{Z}(t), t)], \\ \frac{d}{dt} E_j[V(\mathbf{Z}(t), t)] &= E_j \left[\frac{\partial}{\partial t} V(\mathbf{Z}(t), t) \right] + \sum_{r=1}^2 E_j \left[\frac{\partial V(\mathbf{Z}(t), t)}{\partial Z_r} c_r(\mathbf{Z}(t), t) \right] \\ &\quad + v E_{j-1}[V(\mathbf{Z}(t), t)] - v E_j[V(\mathbf{Z}(t), t)], \quad j = 2, 3, \dots, k. \end{aligned} \quad (114)$$

Introduction

Condition assessment of civil structures is a task dedicated to forecasting future structural performances based on current states and past performances and events. The concept of condition assessment is often integrated within a closed-loop decision, where structural conditions can be adapted based on system prognosis. Figure 1 illustrates a particular way to conduct condition assessment. In the process, various structural states are measured, which may include excitations (e.g., wind, vehicles) and responses (e.g., strain, acceleration). These measurements are processed to extract indicators (e.g., maximum strain, fundamental frequencies) of current structural performance. These indicators are stored in a database, and also used within a forecast model (e.g., time-dependent reliability, Markov decision process) that will lead to a prognosis on the structural system, enabling optimization of

Novel Bio-Inspired Sensor Network for Condition Assessment, Fig. 1 Condition assessment process

structural management decisions (e.g., inspection, repairs, maintenance). The forecast model itself may query information from the database that include past performance indicators and events. One of the fundamental benefits of condition assessment is the availability of condition-based maintenance decisions (CBM), which enables maintenance in function of current and expected conditions rather than based on usage rate (preventive-based maintenance) or breakdown (breakdown-based maintenance). CBM has the potential to significantly improve life-cycle costs and structural resiliency by optimizing maintenance and inspection schedules and forecasting structural behavior (Jardine et al. 2006). It could also be used for automatic assessment of structural conditions following natural hazards (e.g., earthquakes).

The literature on structural prognosis and condition assessment has fundamentally focused on the specialized task of damage diagnosis, including sensing hardware and signal processing methods, but much remains to be done on developing integrated sensing solution that could lead to condition assessment (Jardine et al. 2006). The vast majority of cited work in condition assessment is in the field of machinery, and applications in civil engineering are mostly limited to bridges. See References (Frangopol et al. 2004; Teughels and De Roeck 2004; Perera and Ruiz 2008) for examples. Other specialized civil engineering applications include buildings (Savadkoohi et al. 2011), pipes (Dilena et al. 2011), and wind turbine blades (Abounhnik and Albarbar 2012). While a literature survey indicates a growth in research on condition assessment methods for civil structures, the full potential of these methods is yet to be realized (Farrar and Lieven

2007). Some challenges impeding broad applicability include the needs to develop (1) algorithms enabling real-time decision making; (2) robust sensing systems for online data acquisition; (3) methods for collecting event information; and (4) more accurate forecasting models (Frangopol et al. 2004; Jardine et al. 2006; Farrar and Lieven 2007).

The author has developed a novel sensing method designed for condition assessment of civil structures. The method consists of an array of soft elastomeric capacitors (SECs) acting as flexible strain gages. Arranged in a network, SECs are capable of covering very large areas at low costs. It was demonstrated that a network was capable of covering an area of $70 \times 280 \text{ mm}^2$ with only four sensors (Laflamme et al. 2013a). Analogous to biological skin, the SEC network can localize strain over a global area. The technology is an alternative to fiber optics technologies. With both fiber optic sensors and the SEC technology, strain data can be measured over large systems. Others have proposed alternatives to conventional strain sensing, including conducting cement mixes (Materazzi et al. 2013) and piezoelectric networks (Giurgiutiu 2009). Conducting polymers, such as soft resistors and capacitors, have also gained popularity for structural health monitoring applications (Tata et al. 2009; Loh et al. 2009; Gao et al. 2010). The proposed SEC differs from existing literature in that it combines both a large physical size and high initial capacitance, resulting in a larger surface coverage and higher sensitivity. Also, it combines the advantages of being cost-effective, easy to install, robust with respect to mechanical tampering, and customizable in shapes and sizes, and low powered.

Deployment of the sensor network over large areas allows the measurement of strains over large surfaces. These measurements can be used to reconstruct physics-based features associated with the structural behavior. For instance, the analysis of deflection shapes can give insights on structural performance, whether it is by studying changes in curvature through time, or simply by counting the number of cycles and/or over-stresses. These physics-based features can be integrated into a forecast model to establish the severity of the problem and enable decision making.

In this article, the promise of the SEC network for condition assessment applications is presented. The next section describes the SEC used in the network setup. The description includes a discussion of the fabrication process, the electromechanical model used for converting signal into strain and shows a comparison with off-the-shelf resistance-based strain gauges (RSGs). The subsequent section discusses the application of the sensor in a sensor network for conducting condition assessment. It also describes an algorithm used for extracting physics-based features from the network signal and demonstrates the application. The last section concludes the article.

Soft Elastomeric Capacitors

The proposed sensor network for condition assessment applications has been developed by the author (Laflamme et al. 2012, 2013a). It consists of an array of SECs, a type of conducting polymers. The field of conducting polymers has been pioneered in the 1970s, when it was discovered that polymers can not only be used as insulators but also as conducting mediums (Shirakawa et al. 1977). They have since then been used for various purposes, including flexible sensors and actuators (Osada and De Rossi 2000). These synthetic metals typically originate from the constitution of a nanocomposite mix of organic and inorganic particles, which can be obtained via chemical and electromechanical preparations, as discussed in Reference

(Gangopadhyay and De 2000). Figure 2 shows the principle using scanning electron microscope (SEM) photos, in which an organic material (poly-styrene-co-ethylene-co-butylene-co-styrene (SEBS), Fig. 2a) is mixed with inorganic particles (titanium dioxide (TiO_2), Fig. 2b) to form a nanocomposite mix SEBS + TiO_2 (Fig. 2c).

The SEC is fabricated using the principles of conducting polymers. Figure 3a shows the schematic of a capacitor, constituted from a dielectric sandwiched between two conducting plates that can be connected to an electric charge. It follows that a soft capacitor can be built from an elastomeric dielectric layer sandwiched between compliant electrodes. Here, the dielectric is a nanocomposite mix of SEBS doped with TiO_2 , the same materials showed in Fig. 2. The compliant electrodes are fabricated from a nanocomposite of SEBS and carbon black (CB). Figure 3b shows a picture of a single SEC. In this section, the fabrication process of the SEC is described, its electromechanical model derived, and its performance versus off-the-shelf RSGs compared.

Fabrication

Figure 4 illustrates the fabrication process of a SEC. First, a solution of SEBS dissolved in toluene (solvent) is created. Then, TiO_2 particles are dispersed in part of this solution using a sonication process. The resulting SEBS + TiO_2 mix is spread over a glass slide and allowed to dry, during which phase the solution becomes solid and the toluene evaporates. Meanwhile, the CB particles are dispersed in the remaining SEBS-toluene solution, also using sonication. Finally, this electrode mix is painted or sprayed onto the top and bottom surfaces of the dielectric and allowed to dry.

The SEC's dielectric layer is doped with TiO_2 to improve the sensor's mechanical properties, specifically its dielectric properties. The capacitance value C of a SEC is written

$$C = \epsilon_0 \epsilon_r \frac{A}{h}$$

Novel Bio-Inspired Sensor Network for Condition Assessment, Fig. 2 SEM photos of (a) SEBS, (b) TiO₂, and (c) SEBS + TiO₂

Novel Bio-Inspired Sensor Network for Condition Assessment, Fig. 3 (a) Schematic of a capacitor; and (b) a single SEC (bottom electrode not shown)

where $\epsilon_0 = 8.854 \text{ pF/m}$ is the vacuum permittivity, ϵ_r the dimensionless polymer relative permittivity, $A = wl$ the sensor area with width w and length l , and h the height of the

dielectric. Altering the nanocomposition of the dielectric enables a customization of ϵ_r . For instance, the author has shown that it was possible to dramatically increase the relative

Novel Bio-Inspired Sensor Network for Condition Assessment, Fig. 4 Fabrication process

Novel Bio-Inspired Sensor Network for Condition Assessment, Fig. 5 Sensing principle (layers not scaled)

permittivity of the SEBS by grafting polyaniline (PANI) on the polymer backbone (Kollosche et al. 2011). Here, TiO₂ is used due to the low cost and high stability of the particles.

Electromechanical Model

The sensing principle of the electromechanical sensor consists in measuring strain via changes in capacitance. Figure 5 illustrates the sensing principle for a SEC glued onto a monitored surface using an epoxy. In the example, a strain in the monitored surface provokes a change in the sensor geometry $\hat{l}$. This strain is linearly transduced by a change in the capacitance $\hat{l}^nC$ of the

sensor. This change is measured by a data acquisition system (DAQ).

The SEC materials can be considered as incompressible (the Poisson ratio of SEBS $\nu \approx 0.49$ (Wilkinson et al. 2004)). It follows that the sensor volume V is preserved ($\Delta V = 0$):

$$V = V + \Delta V$$

$$w \cdot l \cdot h = (w + \Delta w) (w + \Delta l) (h + \Delta h)$$

Ignoring higher order terms, the last equation can be written:

$$-\frac{\Delta h}{h} \approx \frac{\Delta l}{l} + \frac{\Delta w}{w}$$

$$-\varepsilon_z \approx \varepsilon_x + \varepsilon_y$$

Also, for small changes in C , the differential of the equation governing capacitance is taken as:

$$\Delta C = \left(\frac{\Delta l}{l} + \frac{\Delta w}{w} - \frac{\Delta h}{h} \right) C$$

$$\frac{\Delta C}{C} = \varepsilon_x + \varepsilon_y - \varepsilon_z$$

Substituting ε_z , the last equation becomes:

$$\frac{\Delta C}{C} = 2(\varepsilon_x + \varepsilon_y)$$

which results in a gauge factor $\lambda = 2$. The equation above shows that the sensor measures additive strain. The principal strain components and magnitudes can be decomposed by leveraging network applications of the SEC. This is out-of-the-scope of this chapter.

While the nanocomposite mix does not influence the gauge factor, it plays an important role in the sensor sensitivity $\frac{\Delta C}{\varepsilon_x + \varepsilon_y} = 2C$. It results that the sensitivity can be improved by increasing the materials permittivity ε_r , resulting in a better resolution. The sensitivity can also be increased by altering the sensor geometry.

Comparison Versus Off-the-Shelf Strain Gauge

In this subsection, a performance comparison between an SEC and an off-the-shelf RSG is presented. Additional details on this comparison can be found in Reference (Laflamme et al. 2013a). The test setup consists of a three-point load setup on a simply supported aluminum beam of support-to-support dimensions $406.4 \times 101.6 \times 6.35 \text{ mm}^3$ ($16 \times 4 \times 0.25 \text{ in}^3$). A SEC and a RSG (Vishay Micro-Measurements, CEA-06-500UW-120, resolution of $1 \mu\varepsilon$) are installed centered onto the bottom surface of the beam. The setup is similar to Fig. 8, except with one sensor of each type, centered. Both sensors are installed following a similar procedure. The monitored surface is sanded, painted with a primer, and a thin layer

of an off-the-shelf epoxy (JB Kwik) is applied on which the sensors are adhered. Data from the SECs are acquired using an inexpensive off-the-shelf data acquisition system (ACAM PCap01) sampled at 48 Hz. RSG data are acquired using a Hewlett-Packard 3852 data acquisition system, and data sampled at 55 Hz. The excitation history consists of a displacement-based triangular wave loads with increasing frequencies from 0.0167 to 0.40 Hz to remain in a quasi-static range.

Figure 6 shows the results from the test. The time series responses from the SEC and RSG are shown in Fig. 6a, along with the loading history in Fig. 6b. Results from the SEC compares well against readings from the off-the-shelf RSG. Figure 7a shows the absolute error between the SEC and RSG readings. The SEC can track the time history with a resolution of 25–30 $\mu\varepsilon$. This resolution could be improved with the fabrication of a dedicated DAQ system (Laflamme et al. 2012). Figure 7b studies the sensitivity of the SEC obtained experimentally versus the theoretical value. The experimental sensitivity of 1190 pF/ ε is close to the theoretical value of $2 \times 600 = 1,200 \text{ pF}/\varepsilon$, a 0.84 % difference. Also, results from Fig. 7b exhibit linearity, consistent with theory.

Sensor Network for Condition Assessment

The previous section described the theory for SECs and showed that it can be used effectively as a large-scale strain gauges. In this section, the SEC concept is extended to multiple sensors installed in an array form, which allows monitoring of large surface areas. In the context of condition assessment, spatial and temporal surface strain data can be assembled, from which physics-based features can be extracted. As discussed in the introduction, these features can be stored, compared, and analyzed to evaluate structural usage, or to detect changes and/or anomalies in the structural behavior. This study of structural behavior can be incorporated in a forecast model to enable prognosis

Novel Bio-Inspired Sensor Network for Condition Assessment, Fig. 6 Strain gauges comparison: (a) time series response; and (b) loading history

Novel Bio-Inspired Sensor Network for Condition Assessment, Fig. 7 (a) Absolute error between the SEC and RSG; and (b) capacitance versus strain for the SEC

of the structural system, with the overarching objective to optimize structural management decisions.

Here, the promise of SEC networks at conducting condition assessment is shown by extracting deflection shapes from the measurements. Remark that the design of accurate forecast models based on signal features is a challenging problem and constitutes an active field of research. Reference (Frangopol et al. 2004) reviews some fundamental forecast models, and constitutes a good introduction to the research problem for the interested reader.

Feature Extraction

Spatial and temporal strain data contain rich information about the monitored system. However, the task of condition assessment cannot be successfully conducted without the extraction of meaningful features from data. The problem is analogous to signals from accelerometers from which, in most cases, frequency features (e.g., fundamental frequencies, mode shapes) need to be extracted to enable the analysis of the vibration signature. Several types of features can be extracted from an array of strain gauges,

including local plastic deformations, overstrains, cycles, and deflection shapes. Here, the concept of the sensor network for condition assessment is demonstrated by extracting deflection shapes from a monitored surface.

The problem of real-time reconstruction of deflection shapes from position and curvature measurements from sensor networks has been widely studied, with applications to condition assessment, structural health monitoring, and shape control. See references (Jones et al. 1999; Glaser et al. 2012); for instance. Here, the algorithm consists of fitting the curvature data using a polynomial interpolation and double-integrating to obtain the deflection shape. In the case of a two-dimensional beam equipped with four sensors, the fitting function is taken as a third degree polynomial to avoid possible over-fitting and also allows some additional filtering on the measured strain data (Jones et al. 1999; Glaser et al. 2012):

$$\hat{\epsilon}_{m,i} = a_0 + a_1 x_i + a_2 x_i^2 + a_3 x_i^3$$

where the *hat* denotes an estimation for the *i*th sensor, a_1 to a_4 are constants, and x is the Cartesian location $0 \leq x \leq L$ along the beam of length L . Minimizing the error J for n sensors:

$$J = \sum_i^n (\epsilon_{m,i} - \hat{\epsilon}_{m,i})^2$$

leads to the expression:

$$\mathbf{A} = (\mathbf{X}^T \mathbf{X})^{-1} \mathbf{X}^T \mathbf{\Xi}_m$$

with:

$$\mathbf{A} = \begin{bmatrix} a_0 \\ a_1 \\ a_2 \\ a_3 \end{bmatrix} \quad \mathbf{\Xi}_m = \begin{bmatrix} \epsilon_{m,1} \\ \epsilon_{m,2} \\ \dots \\ \epsilon_{m,n} \end{bmatrix}$$

$$\mathbf{X} = \begin{bmatrix} 1 & x_1 & x_1^2 & x_1^3 \\ 1 & x_2 & x_2^2 & x_2^3 \\ \vdots & \vdots & \vdots & \vdots \\ 1 & x_n & x_n^2 & x_n^3 \end{bmatrix}$$

The deflection shape $y(x)$ is obtained by integrating the curvature twice:

$$\begin{aligned} y(x) &= \int_0^L \int_0^L \frac{\delta^2 y}{\delta x^2} dx^2 \\ &= \int_0^L \int_0^L -\frac{\epsilon_m}{c} dx^2 \\ &= \int_0^L \int_0^L -\frac{1}{c} (a_0 + a_1 x_j + a_2 x_j^2 + a_3 x_j^3) dx^2 \\ &= -\frac{1}{c} \left(a_0 \frac{x^2}{2} + a_1 \frac{x^3}{6} + a_2 \frac{x^4}{12} + a_3 \frac{x^5}{20} \right) + b_1 x + b_2 \end{aligned}$$

where c is the distance from the surface to the centroid of the beam, and b_1 and b_2 , are constants that can be determined by enforcing boundary conditions. For example, in the case of a simply-supported beam ($y(0) = y(L) = 0$):

$$\begin{aligned} b_1 &= \frac{1}{c} \left(a_0 \frac{L}{2} + a_1 \frac{L^2}{6} + a_2 \frac{L^3}{12} + a_3 \frac{L^4}{20} \right) \\ b_2 &= 0 \end{aligned}$$

Laboratory Demonstration

The method for extracting the deflection shape feature explained in the previous subsection is demonstrated in what follows. Additional details on the test can be found in Reference (Laflamme et al. 2013a). The test setup, shown in Fig. 8, consists of the same aluminum specimen used for the comparison against the RSG, with the number of SECs extended to four in order to create a sensor network. The SECs and RSGs are located under the beam at $x = \{0.20, 0.40, 0.60, 0.80\}L$, and a three-point load setup is used. A similar experimental procedure as in the previous section is used. The objective of this laboratory verification is to extract deflection shapes from the sensor network.

Figure 9 plots the sensors signals during the first triangular load for the SECs (Fig. 9a) and for the RSGs (Fig. 9b). SEC₁ and SEC₄ have closely spaced signals, as it would be expected for strain gauges symmetrically placed, while SEC₃ shows a substantial difference with respect to SEC₂. The

Novel Bio-Inspired Sensor Network for Condition Assessment, Fig. 8 Laboratory setup. (a) Picture of the setup; (b) setup schematic, elevation view; and (c) setup schematic, bottom plan view

Novel Bio-Inspired Sensor Network for Condition Assessment, Fig. 9 Sensors signals for the first triangular load. (a) SECs; and (b) RSGs

signals for the RSGs are coupled, with a small difference that can be explained by small asymmetries in the sensors placement. All SECs, except for SEC₃, underestimate strain with respect to RSGs.

Figure 10a shows the deflection shapes taken at time $t = 40$ s extracted using the methodology previously described. Results are benchmarked against the analytical solution obtained from the Euler-Bernoulli beam theory. The SECs underestimate the deflection shape as a result of the underestimation of strain from SEC₁ SEC₂, and SEC₄. The deflection shape from the RSG is closer to the analytical result, but with a shift

of the maximum deflection to the right. Figure 10b shows the deflection shapes normalized to their maximum unit deflection. Results show that the SECs give a better estimate of the normalized deflection shapes compared to RSGs. The shift of the maximum deflection point can be explained by the slightly higher strain readings obtained with RSG₃ and RSG₄, both located to the right-hand-side of the beam.

The promise of the SEC network for extracting deflection shapes is further investigated by comparing the root mean square (RMS) error of the normalized deflection shapes with respect to the analytical solution. Results

Novel Bio-Inspired Sensor Network for Condition Assessment, Fig. 10 Deflection shapes extracted from the sensors signals. (a) Non-normalized; and (b) normalized

Novel Bio-Inspired Sensor Network for Condition Assessment, Fig. 11 RMS error of the normalized deflection shapes with respect to the analytical solution

are shown in Fig.11 for the entire loading history. The SEC network obtains a more accurate shape than the RSG network beyond an initial level of loading. When the load is around zero, the noise in the sensors signals results in highly inaccurate deflection shapes. The significant difference in performance between both sensors can be attributed to the SECs averaging strain over a large area, while the RSGs measure a localized strain. SECs are less sensitive to placement errors.

Summary

A novel bio-inspired sensing solution has been presented for condition assessment of civil structures. The technology consists of a SEC transducing changes in strain into changes in capacitance. Arranged in a network setup, the technology can be used to extract physics-based features for condition assessment. Comparisons against an off-the-shelf RSG showed that the SEC is capable of tracking a quasi-static strain history at a

resolution in the range of 25–30 $\mu\epsilon$. This resolution is limited by existing off-the-shelf DAQ systems dedicated to capacitance measurements. Laboratory verifications demonstrated the performance of the SEC network at extracting deflection shapes. The study of the RMS error showed that the SEC network provided accurate normalized deflection shapes, with performance levels beyond the RSG network. This performance can be explained partly by the capacity of the SEC to average strain over a large area, unlike RSGs that measure localized strain. Thus, slight misplacement of SECs has minimum consequences on the shape extraction. Given the results from this laboratory demonstration, the SEC network offers great promise as a sensing method for condition assessment of civil structures.

Introduction

Masonry-infilled reinforced concrete frames constitute a significant portion of the building inventory in seismically active regions around the world. Even though early efforts to analyze the behavior of infilled frames (e.g., Polyakov 1960) date back to more than half a century ago, the modeling of the interaction between the frame members and the masonry infill walls is still an active research area.

It is well known that the resistance of an infilled frame is not a simple sum of the resistance of a bare frame and that of the infill wall due to the fact that the load-resistance mechanism of a frame can change as a result of its interaction with the infill. As described in ASCE/SEI 41 (ASCE/SEI 2007) and shown in Fig. 1, when the system is subjected to a horizontal force acting toward the right, the frame tends to separate from the infill wall at the bottom left and top right corners. Compressive contact stresses develop at the other two corners.

A numerical model for the analysis of infilled frames must be able to capture the effect of the frame–infill separation and the development of compressive contact stresses at two of the four

corners of the infill wall. The damage and nonlinear response of the RC frame members and of the infill walls also need to be accounted for. A masonry infill wall can fail by corner crushing, as shown in Fig. 2a, or shear sliding along bed joints, as shown in Fig. 2b. Shear sliding is expected to be important for cases when the mortar bed joints are relatively weak as compared to the masonry units. Another damage mode, which is common for older structures with relatively weak frame members, has diagonal/sliding cracks developed in the infill wall and shear cracks in the reinforced concrete columns, as shown in Fig. 2c.

This entry is aimed to provide an overview of analytical tools that can be used to study the behavior of masonry-infilled RC frames under earthquake loading. It is not intended to be an exhaustive summary of the literature; rather, it will focus on some of the most common and representative analysis methods developed for such structures including their advantages and limitations. In this respect, two types of analysis methods will be considered: (i) simplified, design-oriented analysis tools, and (ii) refined tools based on the finite element method.

Simplified Modeling Using Equivalent Strut Concept

The vast majority of the simplified analysis methods proposed for infilled frames are based on the *equivalent strut* concept, with which the effect of the infill wall is modeled with diagonal struts. An example of this is shown in Fig. 3. The use of diagonal struts can approximately reproduce the frame–infill contact condition and the stress field in the infill walls. Since earthquake ground motions introduce cyclic lateral loading to infilled frames, at least two diagonal truss elements (one for each loading direction) are required to model an infill wall.

Strut Calibration

The use of a single strut for each direction of loading is expected to be adequate when the infill wall is relatively weak as compared to the frame so that failure is expected to occur in the infill

Corner crushing (with flexural hinges in columns). (b) Sliding along bed joints (with flexural hinges in columns). (c) Diagonal/sliding cracks (with shear cracks in columns)

Numerical Modeling of Masonry Infilled Reinforced Concrete Frame Buildings, Fig. 3 Substitution of infill wall with a diagonal strut member for monotonic loading

wall. The width of the equivalent strut depends on the contact length between the infill wall and the adjacent columns, which, in turn, depends on the stiffness of the infill as compared to that of the columns (Stafford Smith 1967; Mainstone 1972). However, the contact length between the infill and the columns and, thereby, the width of the equivalent strut are expected to change as the load experienced by an infilled frame increases and inelastic behavior develops in the masonry wall. Hence, strictly speaking, the effective strut width determined to represent the stiffness of an infilled frame will not be the same as that required to calculate the strength. For determining the lateral stiffness of an infilled frame, ASCE/SEI 41 (ASCE/SEI 2007) recommends the following expression based on the work of Mainstone (1972):

$$a = 0.175(\lambda_1 \cdot h)^{-0.4} \cdot r_{\text{inf}} \quad (1)$$

where h is the height of the column in a centerline representation of the frame geometry, as shown in Fig. 4a, r_{inf} is the length of the diagonal of the infill wall, and $(\lambda_1 \cdot h)$ is a dimensionless parameter representing a relative stiffness coefficient for the masonry infill and the frame, with λ_1 given by the following expression:

$$\lambda_1 = \left[\frac{E_{\text{me}} \cdot t_{\text{inf}} \cdot \sin(2\theta)}{4E_{\text{fc}} \cdot I_{\text{col}} \cdot h_{\text{inf}}} \right]^{\frac{1}{4}} \quad (2)$$

In Eq. 2, E_{me} is the modulus of elasticity of the masonry, t_{inf} is the thickness of the infill wall, E_{fc} is the modulus of elasticity of the concrete in the frame, I_{col} is the moment of inertia of the cross

Numerical Modeling of Masonry Infilled Reinforced Concrete Frame Buildings, Fig. 4 Material model and parameters for an equivalent strut. (a) Infilled frame properties and dimensions. (b) Uniaxial model for masonry

section of the frame columns, and h_{inf} is the height of the infill wall. A number of other expressions have been proposed in the literature to determine the strut width, as summarized in Asteris et al. (2011). The cross-sectional area of the diagonal strut is the product of the width, a , and the thickness of the infill, t_{inf} .

Mainstone's work suggested different effective strut widths for strength and stiffness for the reason mentioned above. However, for computer-based models, it is convenient to have a constant strut width. To this end, one can determine the effective compressive strength of a diagonal strut rather than the actual compressive strength of the masonry. Unfortunately, no general guidelines are available for this purpose. It is not difficult to convince oneself that this strength depends on the failure mechanism of the infill wall, which could be governed by the sliding of the bed joints, corner crushing, or diagonal/sliding failure. The guidelines in ASCE 41 recommend that the resistance of an infill wall be equal to the product of the shear strength of the masonry bed joints and the cross-sectional area of the wall. A different set of guidelines on determining the effective strut width and the shear strength of masonry infill is given in Appendix B of the MSJC code (2011). However, it should be mentioned that the latter is more for design and for performance assessment.

Klingner and Bertero (1976) used strut-based models to simulate the behavior of infilled frames under cyclic loading. They considered

infill walls constructed of reinforced masonry. They established a nonlinear force–deformation law for the struts to capture the strength degradation due to masonry crushing, the tensile resistance contributed by reinforcing steel in the wall, and the stiffness degradation of the infill wall due to damage. They used the prism compressive strength for the determination of the strut peak resistance, assuming that the area of the diagonal struts remains constant. Their analytical models provided satisfactory estimates of the cyclic response of experimentally tested infilled frames.

Ideally, two struts should be used to represent an unreinforced masonry infill wall, with each strut carrying only compression. A material model that can be used for this purpose is the Concrete01 material in OpenSees (McKenna et al. 2000), whose compressive stress–strain law is shown in Fig. 4b. The peak strength of the material model can be calibrated such that the horizontal component of the strut force is equal to a target resistance (e.g., the value stipulated in ASCE 41), $V_{u, inf}$, using the following equation:

$$f'_m = \frac{V_{u, inf}}{a \cdot t_{inf} \cdot \cos \theta} \quad (3)$$

Other stress–strain laws for infills that have been proposed in the literature (e.g., Crisafulli and Carr 2007) can also be used. A study by El-Dakhakni et al. (2003) has suggested that the

Numerical Modeling of Masonry Infilled Reinforced Concrete Frame Buildings, Fig. 5 Multiple diagonal strut model of an infilled frame under lateral loading. (a) Modeling approach. (b) Distribution of total area into multiple struts

material anisotropy of masonry should be accounted for when determining the stress–strain law for the equivalent strut. However, there has been no systematic study to determine whether accounting for the anisotropy will significantly increase the accuracy of an equivalent strut analogy.

The equivalent strut method is an oversimplification of the actual behavior of an infill wall and fails to capture some key failure mechanisms, such as the one depicted in Fig. 2c. A strut model will not account for the possible shear failure of a column that could be induced by the frame–wall interaction. There is no simple solution to overcome this problem. A study by Stavridis (2009) based on detailed nonlinear finite element models has demonstrated that the compressive stress field in a masonry infill wall may not be accurately represented by a single diagonal strut and that a strut model ignores the shear transfer between the beam and the infill. Hence, replacing a wall by a diagonal strut will not lead to a realistic representation of the load transfer from the frame to the wall. Moreover, as mentioned previously, it is not possible to have a single strut width to capture both the initial stiffness and load capacity of an infilled frame.

To represent the load transfer mechanism in a more accurate manner, multi-strut approaches have been proposed in a number of studies (El-Dakhakni et al. 2003; Crisafulli and Carr 2007). Crisafulli and Carr (2007) have proposed a multi-strut approach as shown in Fig. 5. The figure shows that several of the struts are

connected to the columns with an eccentricity, h_z , which is to be calculated using the following equation:

$$h_z = \kappa \cdot \frac{\pi}{2\lambda_1} \quad (4)$$

where κ is a constant which can take a value between 0.33 and 0.5.

The total strut area, A , needs to be distributed among the various truss elements as shown in Fig. 5b. The middle truss element is assigned half of the cross-sectional area of the equivalent strut, and each of the remaining two struts are assigned one fourth of the cross-sectional area. To account for the possibility for sliding along the bed joints, the middle strut is subdivided into two members, which are connected by a horizontal sliding “spring” and also by a vertical spring with large stiffness to enforce the continuity of vertical displacement at the location of the sliding connections. The sliding spring must have a large, penalty stiffness, and the frictional resistance can be estimated based on the amount of normal (gravity) stresses carried by the infill wall before the application of lateral loads.

The multi-strut model described above has been implemented by Crisafulli and Carr (2007) in a panel element, which only has four corner nodes and can be connected to the frame only at the points representing the beam–column joints. Thus, the effect of the frame–infill contact forces on the bending moments of the frame members

cannot be captured by a panel element. For this reason, it seems preferable to avoid the use of a panel element and simply connect the multiple truss elements to a model representing the RC frame. However, this will necessarily require that each column be represented by two beam–column elements.

While a multi-strut approach may better represent the load transfer mechanism in an infilled frame, it is not certain that it will lead to a significant improvement. A validation analysis by Crisafulli (1997) has shown that excellent results can be obtained by the proposed multi-strut; however, the same reference reported that a very careful adjustment of the properties of the model was required to achieve a good agreement. Details of this adjustment were not discussed. In view of the approximate nature of the equivalent strut approach, the additional complications introduced by a multi-strut model may not warrant such efforts.

In view of the aforementioned issues, a reasonable approach is to treat diagonal struts as purely phenomenological models. They can be calibrated in such a way that they represent not only the behavior of infill walls but that of an infilled frame as a whole. Such calibration can rely on experimental data, or in the absence of experimental data, on refined finite element models. Stavridis (2009) has used experimental data and finite element analysis results to derive a set of simple rules to determine ASCE 41-type pushover curves for infilled frames. Such a curve can be used to determine the load–displacement relation for an equivalent diagonal strut so that the overall load–displacement relation of an infilled frame can be captured. However, that study focused on non-ductile RC frames with relatively strong solid brick infill. More studies are needed to develop pushover curves for other infilled frame configurations.

Modeling of RC Frame Members

The RC frame members in a simplified analysis can be modeled using nonlinear beam elements. A variety of force-based and displacement-based beam elements, with lumped plasticity (having inelastic deformations only at end plastic hinges)

or with distributed plasticity, are available in analysis programs (Filippou and Fenves 2004). Many options also exist for modeling the cross-sectional behavior of the beam elements, which relates the stress resultants, namely, the axial forces and bending moments, to the corresponding generalized strains, i.e., the axial strain along the reference axis and the curvature. The most accurate and efficient formulation is the one based on the discretization of the cross section into fibers of concrete and steel reinforcement, with each fiber having an appropriate uniaxial constitutive law.

Shear failure can occur in the columns due to the forces developed from the frame–infill interaction, especially for non-ductile frames with strong masonry infill. If column shear failure is deemed probable, it can be accounted for in the analytical models through, e.g., nonlinear springs representing the shear force – shear deformation relation for the columns. However, this approach must be used with caution, because a strut model neglects many important aspects of the frame–infill interaction, such as the frictional shear transfer along the beam–infill interface and the variation in the axial forces of the columns due to the friction along the column–infill interfaces (Shing and Stavridis 2014). The introduction of shear springs in the columns may lead to unexpected results.

Infilled Frames Under Combined In- and Out-of-Plane Loading

The simplified strut-modeling concept can be extended to the analysis of infilled frames subjected to combined in- and out-of-plane loading. The simplest possible approach is to reduce the in-plane resistance of the strut elements using a reduction coefficient accounting for the out-of-plane force using the following expression (Al-Chaar 2002):

$$R_{i-o} = 1 + \frac{1}{4} \frac{OP_{\text{demand}}}{OP_{\text{capacity}}} - \frac{5}{4} \left(\frac{OP_{\text{demand}}}{OP_{\text{capacity}}} \right)^2 \quad (4)$$

where OP_{demand} is the applied out-of-plane pressure and OP_{capacity} is the out-of-plane capacity of

Numerical Modeling of Masonry Infilled Reinforced Concrete Frame Buildings, Table 1 Values of coefficient λ_2 for determination of out-of-plane capacity of infill walls according to ASCE 41

h_{inf}/t_{inf}	5	10	15	20
λ_2	0.129	0.060	0.034	0.013

the wall, which can be estimated using the following relation proposed in ASCE 41:

$$OP_{capacity} = \frac{0.7f'_m \lambda_2}{h_{inf}/t_{inf}} \quad (5)$$

where λ_2 depends on the height-to-thickness ratio of the infill wall in accordance with Table 1. Equation (5) can only be used if several criteria, which allow the development of arching action in the infill walls, are satisfied. More specifically, the infill wall must be in full contact with the surrounding frame, the ratio h_{inf}/t_{inf} must not exceed 25 and the frame members must be sufficiently stiff and strong to allow the development of the thrusts from arching action. While this approach is conceptually simple, it requires the estimation of the out-of-plane load demand prior to the analysis.

The interaction of in-plane and out-of-plane loading can also be captured by accounting for the out-of-plane flexure of the masonry infill walls in strut-based models. A method proposed by Kadysiewski and Mosalam (2009) uses beam elements to account for the interaction of the axial force and out-of-plane bending. As shown in Fig. 6, each infill wall is represented with a diagonal beam member whose material can develop both tensile and compressive resistance. The member is subdivided into two beam elements which use a fiber section model. Each fiber in the section has the same elastic modulus, but the strength, sectional area, and distance of each fiber from the reference axis of the beam need to be determined so that the simplified model provides the in- and out-of-plane strength values established in ASCE 41 and can also reproduce a target interaction relation between in- and out-of plane resistance.

While the method by Kadysiewski and Mosalam (2009) provides a reasonable generalization of the ASCE 41 recommendations, it still has some issues. First of all, the determination of

Numerical Modeling of Masonry Infilled Reinforced Concrete Frame Buildings, Fig. 6 Modeling approach for infilled frame under combined in- and out-of-plane loading (Kadysiewski and Mosalam 2009)

the properties of each fiber is an underconstrained problem and has no unique solution. While Kadysiewski and Mosalam have proposed a procedure to circumvent this difficulty, there is no sufficient justification for the method they are proposing. Furthermore, other issues exist with the specific model pertaining to the behavior after yielding and also when collapse is expected to occur, because the model cannot capture the strength degradation occurring at the collapse limit state. Thus, further research is required to ensure a more sound calibration process and also capture the strength degradation effect.

Infilled Frames with Wall Openings

The simplified strut approach based on the representation of infill walls with truss elements can also be used for the analysis of structures where the infill walls have openings. A relatively small opening will not have a significant effect on the behavior of an infilled frame, and for this reason strut-based models can still be used with minor modifications. Al-Chaar (2002) has recommended that the cross-sectional area of the diagonal struts be multiplied by a reduction factor, R_i , which accounts for the existence of openings and is given by:

$$R_i = 0.6 \left(\frac{A_{op}}{A_{inf}} \right)^2 - 1.6 \frac{A_{op}}{A_{inf}} + 1 \quad (5)$$

where A_{op} is the area of the openings in an infill wall and A_{inf} is the area of the infill wall assuming

that it has no openings. The above expression can be used for $A_{op} < 0.60A_{inf}$. If the area of the openings in a wall is greater than 60 % of A_{inf} , then the effect of the infill wall can be neglected. Stavridis (2009) has also proposed formulas to account for the effects of an opening on the initial stiffness and strength of an infilled frame.

The current state of knowledge does not allow the establishment of general guidelines for the strut-based modeling of infill walls with openings. Several efforts have been made, especially for infilled steel frames (e.g., Mosalam et al. 1998), but they are far from conclusive. This is the reason why modern evaluation documents such as ASCE/SEI 41 (2007) state that the use of strut-based models for the analysis of infill walls with openings requires judgment and should be conducted on a case-by-case basis. Additional studies are needed to establish appropriate guidelines for truss models that can be applied to perforated infill walls.

Refined Finite Element Models

More refined models, based on the nonlinear finite element method, can be employed for the simulation of infilled frames (Mehrabi and Shing 1997; Hashemi and Mosalam 2007; Stavridis and Shing 2010; Koutromanos et al. 2011). The main advantage of nonlinear finite element analyses is that they can provide detailed information on the initial stiffness, stiffness and strength degradation, and damage pattern of a structure. The analysis of frames with openings in the infill walls poses no additional difficulty, and it can be conducted using the same types of elements and material laws as for solid infill walls.

Analysis for In-Plane Loading

For refined finite element analysis, the fracture behavior of concrete and masonry can be simulated with continuum elements based on the nonlinear fracture mechanics concept. In these elements, cracks are modeled in a smeared fashion, i.e., with a material stress–strain law representing distributed crack development in

a continuum rather than a traction–separation law for individual cracks. The constitutive models for these elements must account for the effect of cracking-induced damage and compressive crushing in concrete and masonry. Various formulations, based on plasticity, damage mechanics, or simplified nonlinear orthotropic laws, are available in a number of analysis programs. The reinforcing steel can be represented with truss elements using uniaxial constitutive laws. Appropriate interface or spring elements can be added in a model to capture the bond–slip behavior of the reinforcing steel; however, Mehrabi et al. (1994) have shown that the influence of the bond–slip effect is normally insignificant for infilled frames.

The use of continuum elements alone to model the behavior of the concrete and masonry materials is expected to provide accurate estimates of the response when the damage is dominated by the crushing of the infill. Special care is required for cases where cracks are dominated by mode II fracture or when cracks are not aligned with the element boundaries, which can be the case for diagonal/sliding cracks in infill walls or diagonal shear cracks in RC frame members. In such a case, cohesive crack interface elements must be added in the model to represent cracks in a discrete manner. These elements use “traction–separation” (stress–displacement) laws capable of describing the mixed-mode fracture behavior of cracks and mortar joints. Different elastic–plastic cohesive crack interface constitutive laws have been formulated and are available in analysis programs. A cohesive crack model formulated by Koutromanos and Shing is presented in Fig. 7. The displacement and stress vectors of the model include a normal and tangential (shear) component, as shown in Fig. 7a. The failure surface of the model, shown in Fig. 7b, is characterized by three key strength quantities, namely, the tensile strength, s ; the cohesive strength, c (which is the sliding resistance of an interface when there is a zero normal compressive stress); and the asymptotic frictional coefficient, μ . It represents a generalized Mohr–Coulomb law. The failure surface translates

Numerical Modeling of Masonry Infilled Reinforced Concrete Frame Buildings, Fig. 7 Formulation of discrete-cohesive crack interface element for finite

element analysis of infilled frames (Koutromanos and Shing 2012). (a) Interface element. (b) Failure surface. (c) Normal tensile unloading–reloading law

N

and shrinks when fracture occurs, so that the effect of strength degradation is captured. The hysteretic behavior of the cohesive element captures the effect of crack opening and closing as shown in Fig. 7c.

The contact condition between the frame members and the infill walls can also be captured in an analysis using interface elements. Alternatively, if the cohesive strength of the frame–infill interfaces is relatively small and if the frictional resistance along the interface can be entirely attributed to Coulomb friction, standard contact formulations included in many commercial programs can be used instead.

Stavridis and Shing (2010) have used the aforementioned scheme to model masonry-infilled RC frames. They have used both triangular smeared-crack elements and interface elements to simulate the behavior of concrete frame members, as shown in Fig. 8a, and quadrilateral

smeared-crack elements and interface elements to model the unreinforced masonry walls, as shown in Fig. 8b. The zero-thickness interface elements used for the mortar joints are only meant to capture the localized mixed-mode fracture along the brick–mortar interface and cannot account for compressive crushing in the mortar. If the compressive crushing of the mortar were to be accounted for, the interaction between the mortar joints and brick units would need to be explicitly accounted for in the analysis. This interaction can strengthen the mortar layer and weaken the brick units and result in a masonry assembly whose compressive strength is between those of the two constituents. Since this interaction is not captured with the use of the zero-thickness interface, it should be accounted for indirectly by adjusting the properties of the continuum elements in compression to represent the compressive behavior of the

Numerical Modeling of Masonry Infilled Reinforced Concrete Frame Buildings, Fig. 8 Discretization scheme to capture strongly localized cracks in the refined

finite element analysis of infilled RC frames. **(a)** Reinforced concrete members. **(b)** Unreinforced masonry panels

Numerical Modeling of Masonry Infilled Reinforced Concrete Frame Buildings, Fig. 9

Comparison of refined finite element analysis with experimental tests on a single-story, single-bay infilled RC frame. **(a)** Load-displacement curves. **(b)** Crack patterns

masonry assembly. For the RC columns, each reinforcing bar in the columns has been divided into multiple truss elements so that each discrete crack will cross the right quantity of reinforcement.

Koutromanos et al. (2011) have used aforementioned meshing scheme with novel constitutive models to successfully capture the global and local response and damage pattern of infilled

frames under static and dynamic loads. One example is shown in Fig. 9.

Analysis for Combined In- and Out-of-Plane Loading

Refined finite element analysis can also consider combined in- and out-of-plane loading. For this purpose, three-dimensional interface elements need to be used with three-dimensional

Numerical Modeling of Masonry Infilled Reinforced Concrete Frame Buildings, Fig. 10 Calibration of refined constitutive models for concrete. (a) Uniaxial compression (calibration with uniaxial tests on concrete

cylinders or masonry prisms). (b) Uniaxial tension (calibration with splitting tension tests on concrete cylinders or brick units)

continuum elements or shell elements with smeared-crack formulations. While the current state of the knowledge in material models and element formulations allows the use of three-dimensional finite element analysis for infilled frames under combined in- and out-of-plane loads, there have been relatively few such studies. Hashemi and Mosalam (2007) have used shell elements to model the infill walls subjected to combined in- and out-of-plane loading.

Calibration of Constitutive Models for Nonlinear Finite Element Analysis

Refined constitutive models for continuum elements and cohesive crack interface elements typically include many parameters, which require calibration with data from material tests. Data from uniaxial compression tests on concrete cylinders can be used for the calibration of the continuum material models for the concrete, as shown in Fig. 10a, while data from masonry prism tests (uniaxial compression and bond wrench) can be used for the calibration of the constitutive models for the masonry. Interface elements typically include parameters pertaining to mixed-mode fracture, and data from mixed-mode fracture tests on concrete or masonry mortar joints need to be used for the calibration (e.g.,

Hassanzadeh 1990). For mortar joints in masonry infill walls, the tensile (bond) strength typically ranges between 275 kPa (40 psi) and 690 kPa (100 psi), while the frictional coefficient ranges between 0.65 and 0.90.

An important aspect regarding the calibration of continuum elements that have material laws with strain softening is to avoid the spurious mesh-size sensitivity, which will lead to the loss of objectivity of the numerical results. This is caused by strain localization, as explained, e.g., in Bazant and Planas (1998). To remedy this problem, the softening portions of the stress-strain laws will require regularization, i.e., adjustment to account for the element size. In addition, one needs to consider the fact that in the meshing scheme shown in Fig. 8a, tensile cracking can occur in both the continuum elements and the discrete-cohesive crack interface elements. Obviously, the two types of elements should be calibrated to give identical tensile stress-versus-fracturing displacement behavior, as shown in Fig. 10b. For the continuum elements, the fracturing displacement is equal to the product of the inelastic strain, ϵ^f , times the characteristic element length, L_{ch} . The area under the stress-fracturing displacement curve is a material constant called the mode I fracture

Numerical Modeling of Masonry Infilled Reinforced Concrete Frame Buildings, Table 2 Values of constant G_{fo}^I for determination of tensile fracture energy of concrete (Fib 1999)

D_{max} , mm (in)	8 (0.31)	16 (0.63)	32 (1.26)
G_{fo}^I , N/mm (lb/in)	0.025 (0.14)	0.030 (0.17)	0.058 (0.33)

energy or tensile fracture energy, G_f^I . The following expression, which is proposed in FIB (1999), can be used for the determination of G_f^I :

$$\begin{aligned} G_f^I &= G_{fo}^I \left(\frac{f_{cm}}{f_{cmo}} \right)^{0.7} & \text{for } f_{cm} \leq 80 \text{ MPa} \\ G_f^I &= 4.3 G_{fo}^I & \text{for } f_{cm} > 80 \text{ MPa} \end{aligned} \quad (6)$$

where f_{cm} is the mean compressive strength of the concrete, f_{cmo} is equal to 10 MPa (1.46 ksi), and G_{fo}^I is a reference value of the fracture energy, which represents the fracture energy for concrete with a compressive strength equal to 10 MPa, and it depends on the maximum aggregate size, d_{max} , as shown in Table 2. The fracture energy for the masonry units and for the mortar joints can be calibrated using data from experimental tests (e.g., van De Pluijm 1997).

Often, there may not be sufficient material test data to calibrate all the material parameters in a finite element model. In such cases, a sensitivity analysis is required to determine the sensitivity of the numerical results to the values of parameters that cannot be determined from material test data. A parametric study by Stavridis and Shing (2010) with finite element models has indicated that the shear strength parameters for mortar joints are most influential on the load–displacement response of an infilled frame.

Determination of Gravity Load Distribution Between Frame Columns and Infill Walls

The behavior of an infill wall strongly depends on the compressive stress in the bed joints. An increased gravity load will increase compressive stress and, thereby, the resistance of the bed

joints, thus increasing the stiffness and strength of a wall. An accurate estimate of the gravity load distribution between the infill wall and the surrounding frame is necessary to ensure that the analysis provides accurate estimates of the strength and stiffness of the system. The most straightforward approach to estimate the gravity load distribution for existing structures is to use in situ tests with flat-jacks. Since it may not always be feasible to conduct such tests, analytical models may be used to estimate the fraction of gravity loads carried by the frame columns and infill walls, respectively.

The analytical determination of the gravity load distribution between the frame and the infill wall requires several considerations. First, a part of the gravity loads may be applied onto the RC columns before the construction of the infill walls because these walls could be constructed after the frame has been completed. Second, long-term effects such as concrete and masonry creep, concrete shrinkage, and brick masonry expansion with time due to water absorption can significantly affect the gravity load distribution. While refined finite element models with viscoelastic material properties can be employed for the determination of the gravity load distribution, the increased computational burden of such analyses may not necessarily produce results of increased accuracy due to lack of experimental data to allow the calibration of multiaxial viscoelastic constitutive models.

Based on the above consideration, simplified models are deemed preferable for the determination of the gravity load distribution, since they are easy to calibrate and their reliability is not necessarily inferior to that of more refined models. Such a simplified physical model is shown in Fig. 11a. The model consists of springs and dashpots to represent the instantaneous axial stiffness and the viscoelastic (creep) properties of the RC columns and the masonry infill. The “gap” u_o , shown in Fig. 11a, corresponds to the short-term deformation of the columns due to the gravity loads that are applied before the construction of the infill walls. The spring-and-dashpot assemblages representing the concrete columns and masonry walls can be calibrated with data from

Numerical Modeling of Masonry Infilled Reinforced Concrete Frame Buildings, Fig. 11 Simplified physical model for the estimation of the gravity load

creep tests on concrete and masonry; Fig. 11b shows an example of the calibration of a creep model for concrete. The effect of the brick expansion can also be easily added in the model. A detailed explanation of the simplified modeling approach and of how the gravity load distribution can be correctly modeled in a finite element model is given in Koutromanos (2011).

Summary: Concluding Remarks

The modeling of infilled frames is a challenging task because a variety of failure mechanisms may affect the load-resistance properties of the system. The analysis can be conducted using simplified models based on the equivalent strut concept or refined finite element models using appropriate constitutive models for the materials. Strut-based models are conceptually simple and easy to calibrate and implement, but their accuracy is inherently limited, especially if walls with openings are to be analyzed. It is not certain whether the use of complicated multi-strut models is meaningful, because such models are bound to misrepresent some important mechanisms that can develop in infilled frames. On the other hand, refined finite element models are more general and realistic, but the efforts on the calibration of the constitutive models and preparation of such analyses are much more significant. Furthermore, refined finite element analyses are computationally

demanding. Thus, the selection of the modeling approach depends on the desired level of accuracy, the expertise of the analyst, and the time and computational resources available for the analysis.

OBS

Introduction

About 70 % of the world is covered by oceans. Because of the difficulty of accessing the ocean floor, most of the seafloor and the crust below was unexplored for a long time. In the early 1930s, the seismic refraction method was developed and geoscientists tried to develop techniques to use this method offshore. They experimented with cabled sources and geophones but also with free-fall instruments. The first layout of a stand-alone ocean-bottom seismometer (OBS) was published in 1938 (Ewing and Vine 1938) and tested in the years 1939–1940. This OBS used a gasoline-filled rubber balloon for buoyancy, which floats approx. 3 m above the seafloor.

An aluminum housing containing an automatic oscillograph was mounted below the balloon. The iron ballast and the external geophone for recording man-made explosive seismic signals were located on the ocean bottom (Ewing et al. 1946).

After these first experiments, there were only intermittent OBS deployments until the late 1950s and early 1960s, where seismic monitoring of nuclear explosions became suddenly important. For this purpose, a uniform monitoring station distribution around the globe was desired, so seismic stations in the oceans were necessary. Programs like the “Vela Uniform project” promoted advancements in OBS technology (VESIAC 1965). Since then, the usage of OBS for passive earthquake recording and active-source experiments has become more and more common, as many scientific targets are located offshore, including continental margins, mid-ocean ridges, gas and oil reservoirs, and potential tsunami-generating areas.

Today, a great variety of OBS exist for different scientific purposes: short-period instruments mainly for active-source experiments, broadband seismometers for passive earthquake recording, small-sized OBS for short-term deployments, and larger platforms with independent operating times of 1 year or more. Technology developed rapidly since the first OBS deployments, but the principle remains the same: an instrument carrier, equipped with one or more sensors, a data logger with batteries, and a release unit, is weighted with some ballast anchor and sinks freely down to the

Ocean-Bottom Seismometer, Fig. 1 Stacked OBS frames with floatation consisting of glass spheres (*left*) and syntactic foam (*right*) (Photographs W. Crawford, Paris (*left*) and M. Schmidt-Aursch, Bremerhaven (*right*))

seafloor to record autonomously natural or man-made seismic signals. After a certain time or after receiving a hydroacoustic signal, a release unit detaches the anchor and the OBS ascends to the sea surface using some kind of buoyancy. The instrument can then be recovered to retrieve the data for further processing and interpretation.

Besides these free-fall and pop-up ocean-bottom seismometers, there also exist systems with real-time data transfer using moorings or cables. These are sometimes also called ocean-bottom seismometers, although they belong to the category of ocean-bottom observatories. This entry gives an overview of the principles of self-contained OBS without cable connection or any other telemetry, introduces the state of the art of the main component technologies, and explains the special demands of OBS data processing.

General Hardware Requirements

Ocean-bottom seismometers are deployed in a rather hostile environment: the seafloor. Ambient temperatures are low, the ambient pressure is high, and water salinity causes metal parts to

corrode. The seismometer should be well coupled to the seafloor and withstand water currents, and the instrument should cause as little noise on the seismometer as possible. The stations might face high accelerations and shocks during handling on the ship's deck, during deployment and recovery, and on touchdown at the seafloor. An OBS must therefore be mechanically robust and solidly built. Pressure casings for water depths of several thousand meters – a water pressure of tens of MPa – must have thick and homogenous walls, and the floatation must be highly incompressible. To resist shocks, the frame, buoyancy, and all other parts must be of rugged design.

On the other hand, the instruments should be as compact as possible, because transport costs are high and deck space is limited on most vessels. Most OBS designs allow stacking of the frames and the floatation (Fig. 1) and storing the other parts in standard transport boxes. As ship time is limited and expensive, the instruments should be easy to mount so that a large number of units can be prepared in a short time. The mounted devices must be able to be handled on deck and by crane during bad weather conditions. For recovery, easy sighting of the instruments in the waves and a safe pick up from the sea surface is desirable. There is no ideal OBS design to

satisfy these specifications; therefore, various designs have been developed that are optimized for specific purposes, like especially compact and light-weighted OBS for active-source experiments, using large numbers of instruments or particularly solid units with larger internal volumes for long-term deployments (Fig. 2).

The harsh conditions offshore also require enhanced specifications for the electronics. All electronic parts must be shock resistant: this is a challenge for sensitive instruments like broadband seismometers or the most common data storage devices. Cables and connectors outside of the pressure tubes must be watertight, saltwater resistant, and designed for high pressures.

Placed on deck of a ship, OBS are exposed to a wide temperature range as the vessel might operate in the sunlit tropics or in polar regions where even the water temperatures are below zero. Therefore, the electronics must be able to operate over a large temperature range. Batteries are so far the only power supply at the seafloor for untethered systems; hence, all components must have low power consumption. In contrast to onshore stations, limited or no maintenance is possible on the ocean bottom. Most OBS can receive some remote-control commands, but for the acoustic link, the presence of a vessel is necessary. The instruments must therefore be highly reliable during long-term deployments.

Instrument Carrier

Frame and Floatation

The base of every OBS is some kind of frame, on which all the other components are mounted. The frame must resist high pressures at the deep sea and the chemically aggressive subsea environment. It must be rigid and stable enough to carry all attaching parts, but on the other hand, it should be as compact and easy to handle as possible. These structures are mostly built of aluminum or titanium alloy or some synthetic material like, e.g., polypropylene. Aluminum alloy is lightweight and cheap, but not as resistant against corrosion as the more expensive titanium alloy. Synthetic materials are rust-free but the frames need larger diameters or thicknesses to reach the same mechanical strength as the slim metal carriers. Figures 2 and 3 present three different OBS types with structures built of aluminum, high-density polypropylene, and titanium alloy.

The frame needs some buoyancy to ascend to the surface after termination of the seismic measurements. The floatation must withstand very high pressures up to tens of MPa in a couple of thousand-meter water depth. The first OBS prototypes used oil- or gasoline-filled rubber balloons for floatation. The densities of oil and gasoline are lower than the density of water, and in addition, oil and gasoline are nearly incompressible. Therefore, the balloons kept their volume and hence their static buoyancy also in deep water. Soon the application of evacuated glass spheres as floatation was developed; their usage is still very common today. They are lightweight and can simultaneously be used as housing for seismometers and other electronic parts. Figures 2 and 3 (right) show a very compact short-period OBS mainly designed for active-source experiments, where the seismometer, data logger, batteries and recovery strobe light, and radio beacon are integrated into the buoyancy glass sphere. Larger OBS for long-term deployments need a couple of spheres to achieve enough buoyancy to carry two or more pressure cylinders full of electronics and batteries back to the surface (Figs. 2 and 3, top). Glass spheres are very shock sensitive; therefore, an additional plastic casing

(e.g., polyethylene) is necessary. If a glass sphere contains electronics, the casing must be perforated to allow access to connectors or to provide visibility of internal flash lights. Nevertheless, they risk implosion at the seafloor and hence the loss of the instrument.

Since the early 1960s, syntactic foam has also been used for floatation. Syntactic foam is a synthetic compound of hollow particles in a background matrix of ceramic, metal, or polymer. An epoxy matrix with hollow glass microballoons with diameters less than 1/100 mm is widely used for deep-sea floatation. This foam is highly incompressible, showing a small reduction in buoyancy only after several years of deep-sea deployments. Syntactic foam can easily be customized to various shapes like plates, blocks, or barrels, so customized OBS designs are possible (Figs. 2 and 3, bottom left). Floatation units made of syntactic foam are robust and easy to handle but much heavier than the glass spheres. The majority of OBS floatation is painted in signal colors to help in spotting the instrument after emerging at the sea surface.

Anchor Weight and Release Unit

An anchor weight is necessary for the OBS to sink to the seafloor. Most anchors are made of untreated metals like iron or steel; some models also use concrete blocks. The entire system of the frame, sensors and batteries, floatation, and anchor must be carefully balanced in air as well as in water. The weight or buoyancy is different in salt water, freshwater, and air, so a good calculation of buoyancy is necessary. The OBS should sit solidly on the deck, hang well balanced beneath a crane, and should sink and rise in the ocean without swinging or rotating. It must have enough weight and a low enough center of gravity in water to be stable at the seafloor, resisting bottom currents and providing a good coupling of the seismometer to the ground. On the other hand, the impact of the OBS on the sea bottom at deployment should be smooth to avoid damage, especially to the sensitive seismometer. If the instrument weighs too much in water or sinks too fast in the water column, it might sink deep enough into soft sediments to be stuck.

Ocean-Bottom Seismometer, Fig. 3 Sketch of ocean-bottom seismometers. *Top:* OBS with a mechanically isolated broadband seismometer and differential pressure gauge for long-term deployments. *Left:* OBS with integrated wideband seismometer and hydrophone for

long-term deployments. *Right:* Compact OBS with integrated short-period seismometer and hydrophone for short-term deployments (Drawing adapted from Auffret et al. (2004))

A central element of an OBS is the release unit, which connects the frame with the anchor weight. After a certain time (timed release) or on receiving an acoustic command (acoustic release), the release unit disconnects the anchor from the OBS and the OBS can rise freely to the sea surface. The ballast remains at the bottom where it degrades naturally. There are two main release mechanisms: a burn wire or a motor-driven turning hook. A motor-driven releaser clamps the anchor with a hook that is held by a

bolt (Fig. 4, right). The bolt turns mechanically, the hook is released, and finally the anchor is decoupled. A burn wire release holds the anchor using a wire that is partially exposed to seawater. A second larger wire or metal post is also exposed to seawater. When a positive voltage is applied between the wire and the post, electrolysis corrodes the wire, which then breaks, releasing the anchor (Fig. 4, left). The “burn” time depends on the length and thickness of the exposed wire: 10–15 min is typical for many systems.

Ocean-Bottom Seismometer, Fig. 4 Example of release units. *Left:* motor-driven release unit with integrated transducer (Photograph M. Schmidt-Aursch, Bremerhaven). *Right:* burn wire mechanism (Photograph courtesy of A. Ndiaye, INSU, Paris)

Most release units can also send back a response, allowing a two-way hydroacoustic link to the OBS, e.g., to determine the distance to the system, to ask for state of health, or to send simple commands. Some research vessels are equipped with permanently installed transducers, but more often, mobile transducer systems are used on board. For the mobile units, the ship has to stop and the transducer lowered into the water to achieve a coupling of the acoustic signal to the water column. The hydroacoustic signal uses frequencies between 5 kHz and 20 kHz with different modulation techniques. Normally, the signal is coded; each unit uses unique codes for release and other commands. Because the release unit is the central component to recall the OBS, its power supply is usually completely independent from the main system. Some models even use

independent batteries for communication and for activating the release.

Flag, Radio Beacon, and Flasher

After an OBS reaches the surface, the next challenge is to recover it. The OBS is small compared to the area of the ocean in which it may surface and local currents might make the OBS drift away from the deployment position on its way down and up through the water column. After emerging at the surface, currents and wind may also move the OBS away. Waves and decreased visibility due to rain or fog can hinder the search. Painting the OBS with a signal color (yellow, orange, or red) helps observers to spot the instruments. A flag can also help sighting OBS at large distances or in tall waves, but high-profile flags can also generate noise on the data, so not all OBS have flags.

However, almost all OBS are equipped with a VHF radio beacon and a Xenon flasher (Fig. 5, middle and left). The casing of the beacons is usually made of aluminum and the radio antenna is made of steel, so sacrificial anodes are necessary to avoid electrolytic corrosion of the aluminum. The radio beacon and strobe both contain a pressure switch that turns the units off at 1–10-m water depth to save battery power while the instruments are at the seafloor. The strobe light additionally uses a light sensor that only allows flashing in the dark, also for battery saving purposes. The flashers are especially useful during night, the light can be spotted over larger distances than the flags, but the estimation of the station distance is more difficult than during daylight.

Radio beacons are available with different frequencies or different transmitting cycles to distinguish individual OBS in case that several instruments are “on the air” at the same time. The majority of VHF beacons operate in nautical frequency bands, so besides handheld direction finders, also shipborne cross bearing receivers can be used to determine the direction of the radio signals. The signal range at the sea surface is quasi-optical, which means approximately to the optical horizon, from elevated locations or helicopters, the OBS can be located over

Ocean-Bottom Seismometer,

Fig. 5 Example of a Xenon flasher (*left*), VHF radio beacon (*middle*), and a satellite transmitter (*right*) (Photograph M. Schmidt-Aursch, Bremerhaven)

distances of several tens of kilometers. Some models integrate a GPS system and send position data using the “Automatic Identification System” (AIS) that is mandatory for many vessel classes. There are also beacons that send an identifying signal to a satellite after emerging at the sea surface (Fig. 5, right). The operator then receives an email containing the position of the OBS. This remote surveillance technique is especially useful, if the station rises ahead of time or is caught by a trawler, but the transponders are bulky and costly, require additional license fees, and are therefore not widespread.

Sensors and Data Logger

Seismometer

The main purpose of an OBS is to record seismic signals on the sea bottom; therefore, a seismometer specially adapted to the marine environment is necessary. For active-source experiments (using man-made sources) or local seismicity

studies, a short-period seismometer, sometimes also called geophone (Greek for “earth sound”), is sufficient. The most common are the three-component seismometers with a corner frequency of 4.5 Hz. These passive analog sensors consume no power and are relatively compact. Either they are mounted in a small pressure casing on the frame of the instrument or they can even be integrated into the main casing with other electronics (Fig. 3, bottom right). Some models are equipped with detachable seismometers, which are normally released by a burn wire or corrosion mechanism after arriving at the seafloor. High-frequency geophones are often leveled, usually with a passive, gravity-based system, a so-called gimballed system.

To study lower-frequency signals, a wideband or broadband seismometer is required. For offshore deployments, broadband seismometers with a pass band out to 120–240 s are available, but wideband seismometers with a pass band out to 30–120 s are more common because of their smaller size and lesser power consumption. These active wide- or broadband seismometers output one vertical and two horizontal components. Similar to onshore stations, the seismometers must be perfectly leveled in order to work properly: in fact, it is even more important at the seafloor because seafloor currents can create noise on the horizontal component that rotates on to the vertical component if the seismometer is not perfectly leveled (Crawford and Webb 2000). Because the tilt of the OBS on the seafloor is unknown, all wideband and broadband seismometers contain an automatic electromechanical leveling system (Fig. 6). Leveling is activated some hours after the OBS arrives at the seafloor and is usually repeated from time to time for long-term deployments. Care must be taken not to level (or even check the level) too frequently, as the switching on of the leveling circuitry can introduce a noise spike in the data. There are several ways to level either the entire seismometer package or each component separately. Some models are gimbal mounted in two directions (Fig. 6); other models contain only one gimbal but additionally turn the seismometer until all three components are leveled.

Ocean-Bottom Seismometer,

Fig. 6 Example of a broadband seismometer (*green sphere*) mounted in a two-axis gimballing system. The pressure case was removed (Photograph W. Crawford, Paris)

For all seismometers, a good coupling to the seafloor is essential. Two main approaches are in use today: integrated and mechanically isolated seismometers. Integrated seismometers are fixed directly to the instrument carrier and coupling is provided by the entire system including the anchor weight (Figs. 2 and 3, bottom). These systems are tightly arranged and easy to handle during deployment and recovery. Mechanically isolated seismometers have their own pressure case and are normally mounted on a deployment arm (Figs. 2 and 3, top). The sensor package is automatically detached when the station reaches the ocean bottom. These models are more complex, but movements or tilting of the instrument carrier will not be transmitted to the seismometer. The best coupling would be achieved by burying the seismometer into the sediment (e.g., Duennebie and Sutton 2007), but unfortunately all these instruments still need support from remote-operating vehicles (ROV) for deployment and recovery, which makes such experiments very expensive and time-consuming.

Pressure Sensor

Besides the seismic channels, the majority of OBS types provide a fourth channel recording the signals of a pressure sensor. In water, pressure is much easier to measure than displacement or acceleration. Pressure is omnidirectional, so a single channel is sufficient and no special coupling to the surrounding water is necessary.

For applications only interpreting compressional waves (P-waves), like some active-source experiments, the so-called ocean-bottom hydrophones (OBH) can be used. This kind of instrument is equipped solely with a hydrophone. When combined with three-component seismological data, the additional pressure channel can be used to remove water-bounce phases from seismic signals (the pressure and seismic signals from water bounces have different polarities; see Blackman et al. 1995) and at low frequencies (less than approximately 0.1 Hz) remove low-frequency noise on the vertical seismometer channel (Webb and Crawford 1999) and determine the physical properties of the seafloor (“seafloor compliance,” e.g., Crawford et al. 1991).

The overall bandwidth of hydrostatic pressure in the oceans is large; it starts at 100 KPa at the sea surface and increases by 10 Mpa per thousand-meter water depth. Compared to this, pressure changes caused by earthquakes are very small (generally less than 1 Pa). An instrument that is able to adapt to the large pressure range as well as to detect small pressure changes over the entire seismic band would be very complex and power consuming. Therefore, various sensors exist, which are optimized for specific purposes. There are absolute gauges quantifying the entire hydrostatic pressure, or differential units, which adapt to the mean surrounding pressure and record only the small changes.

Ocean-Bottom Seismometer,

Fig. 7 Examples of pressure sensors. *Left:* instrument carrier with a differential pressure gauge (DPG) and an absolute pressure gauge (APG). *Right: APG (top),* hydrophone (*middle*), and DPG (*bottom*) (Photographs M. Schmidt-Aursch, Bremerhaven and W. Crawford, Paris (*top right*))

The simplest differential pressure sensor is an analog hydrophone (Fig. 7, middle). The first hydrophones were utilized during World War I, mainly to detect submarines. There are several ways to convert pressure changes into electricity, including moving coils in solenoids actuated by membranes and interferometric fiber-optic coils, but most OBS are equipped with a pressure-compensated hydrophone using the piezoelectric effect. It consists mainly of a piezoelectric ceramic cylinder, which linearly generates a voltage when opposed to mechanical stress. The entire system is encapsulated in an elastomer, e.g., polyurethane. Hydrophones are compact, passive sensors that need no additional power supply unless they integrate a preamplifier. Similar to seismometers, hydrophones are available in various short- and long-period versions with frequencies from approx. 50 kHz down to 0.01 Hz. The hydrophone acts electronically as a capacitor; therefore, the high-impedance input of the data logger must carefully be adapted to achieve both short settling times at the seafloor and linear sensitivity down to very low frequencies.

Differential pressure gauges (DPGs, Cox et al. 1984) can measure pressure signals from approximately 0.0005 Hz to 40 Hz and are

popular on broadband OBS. Differential pressure is measured between a reference chamber and the ocean using a strain gauge with small dynamic range (Fig. 7, left and bottom, and Fig. 8). The reference chamber and the gauge around it are filled with silicon oil, and the gauge is left open to ocean pressures by a soft membrane. The pressure in the reference chamber is kept close to that of the ocean using a capillary leak and, for deployment and recovery, overpressure relief valves. The capillary leak creates a high-pass filter whose corner frequency depends on the tube's diameter and length as well as the viscosity of the oil within the gauge; typically, a value of 0.002–0.004 Hz is sought. These gauges have proven difficult to calibrate accurately. In principle, changes in the viscosity of the oil with temperature and pressure should change the high-pass corner frequency, but in practice the biggest uncertainty has proven to be the absolute gain which appears to be 15–20% lower than that measured by an absolute gauge, even for DPGs that were carefully calibrated in the laboratory.

Absolute pressure gauges (APGs, Fig. 7, left and top) can be used to measure pressures from approximately 1 Hz to DC. The most commonly available absolute pressure gauges for ocean floor experiments had, until recently, a noise floor of

Ocean-Bottom Seismometer, Fig. 8 Sketch of a differential pressure gauge (DPG)

about 10 Pa, but sensitivities are now down to about 0.1 Pa. APGs are expensive and power hungry, but they are usually very well calibrated and they can also measure tsunamis and seafloor vertical motions. The pressure is measured by counting the oscillations of a quartz crystal resonator, which is different from the voltage-based signals from hydrophones, DPG, and seismometers. Several commercial companies sell absolute pressure gauges designed for full ocean depth: one possible configuration would be to deploy an APG sampling at a relatively low rate strapped on to an OBS containing a hydrophone.

Data Logger

The analog signals of the sensors are recorded by a data logger. The technology has evolved a long way from the early photographic oscillographs to the present-day 24-bit digitizers with solid-state-disk storage media, and development continues rapidly. Many efforts have been made to provide the same technical specifications – like dynamic range or size of data storage – for OBS as for onshore stations. Nevertheless, this has not been fully possible because of the added requirements

of seafloor stations: besides stringent requirements for mechanical and electric robustness, seafloor operations demand small dimensions (to fit into the pressure cases), low power consumption (to enable fully autonomous long-term deployments), and a high-precision clock. Size and power consumption are decreasing and data quality and storage are increasing continually as technology advances, but timing is still an issue.

Onshore stations can receive wireless time signals (e.g., DCF77 or GPS) to synchronize the internal clock. On the seafloor, this is unfortunately not possible, so great efforts have been made to develop high-precision clocks. Temperature-stabilized clocks using miniature ovens have been used but they are generally power hungry. Most loggers currently use as their time base temperature-compensated, microprocessor-controlled crystal oscillators (MCXO) with a frequency deviation in order of 10^{-7} to 10^{-8} . Chip-scale atomic clocks (CSAC) with much higher accuracy up to 10^{-10} may be used in the future, but they consume currently more power than crystal oscillators and there are some reliability/aging issues. The internal clock of the data logger is synchronized to an external time signal (e.g., GPS) before deployment and after recovery to determine the drift (“skew”) of the clock. Modern standard clocks show drift rates less than 500 ms/year. The clocks should not only feature a small absolute drift, drift rates should be constant over time to enable a linear time correction of the data afterward. Constant seafloor temperatures contribute to this, but large temperature contrasts and mechanical stress during deployment and recovery must be balanced by the system. For safety reasons, a backup battery independent from the main power supply is desirable for the internal clock.

Specific Requirements of Data Processing

Location of OBS

In contrast to onshore stations, for which the exact location can easily be determined, only the deployment position of the OBS is known.

Most OBS sink relatively slowly to the seafloor (less than 1 m/s) to prevent a hard impact on the ground, so, especially for large water depths, there is much time for currents to push the station away from the direct path. Depending on instrument design, current speed, and sinking time, an OBS might drift several hundreds of meters before reaching the bottom. This discrepancy is too high for experiments mapping small-scale subsurface structures with active sources and specially designed passive arrays that need exact station spacing.

Deployed OBS can be located with the help of the acoustic release unit. Most release units can respond to the onboard unit and the onboard unit can calculate the two-way travel time. Using the sound speed in water enables a calculation of the distance to the station, and ranging from different positions allows a triangulation of the OBS location at known water depth. For good constraints, the instrument should be ranged at from at least three points at approximately equal distance on a circle around the OBS-presumed position. The farther the interrogation, the better the horizontal resolution, but the instrument stops responding beyond some distance, often similar to the water depth. If the water depth is not exactly known, a ranging directly over the instrument is required. Some onboard units are equipped with more than one transducer, and small travel time differences of the response at the transducers can be used to determine the bearing to the station, allowing positioning (in theory) from a single point. Together with the ranged distance and known water depth, the location of the instrument can be determined.

If the OBS experiment is combined with multichannel or wide-angle seismics, the recorded airgun shots of the seismic profiles can be used to determine the position of the instrument on the seafloor. The calculation will be done after recovery; no additional ranging with the onboard unit is necessary. The procedure is similar to the direct ranging via the acoustic release unit; at least three shots evenly distributed around the OBS are necessary. Knowing the exact time and position of the shots, the sound velocity of water, and the water depth, the distances between

shots and OBS and hence the location of the instrument can be computed from the first arrivals of the water wave in the seismograms.

Orienting Horizontal Components

In a free-fall deployment, no method is known to assure that the OBS seismometers' north axis is aligned with geographic north. For active-source experiments, the orientation of the horizontal components is not always important, but it is essential for many passive seismological methods (e.g., receiver functions, shear wave splitting). There are two main approaches to identify the OBS orientation: direct determination by an additional sensor or indirect estimation by analyzing the seismological data.

The simplest direct determination of the orientation would be an electronic compass measuring the three components of the Earth's magnetic field and subsequent calculation of the seismometer's orientation with respect to magnetic north. Unfortunately, magnetic compasses are strongly affected by large metal parts (e.g., anchors) and local variations of the declination, which can be large, especially in volcanic areas. Fiber-optic gyros could be an alternative as they compute the true north direction by measuring the rotation of the Earth, but these sensors are still too expensive and power consuming to be installed on OBS as a standard. Microelectromechanical systems (MEMS) could offer an efficient solution in the future. MEMS accelerometers and gyroscopes, which are widespread in inertial navigation and portable electronic devices like mobile phones, would record accelerations and rotations of the instrument on its way through the water column. The spatial orientation of the instrument could then be calculated for each moment, from the initial point on deck, where the orientation of the OBS is well known, to the final arrival at the seafloor. With this method, the known orientation of the station on deck could be transferred to the sea bottom, but the MEMS systems are not yet stable and precise enough to cope with the intense movements of an OBS during deployment.

The horizontal orientation of the seismometer can also be estimated by analyzing the recorded data. The polarity of P-wave arrivals from

explosives or airgun shots can be used to determine the orientation of the sensor (e.g., Anderson et al. 1987), but in most cases no sources with equally distributed azimuths are available. Instead of man-made signals, the polarization of P- and Rayleigh waves from teleseismic events can be analyzed (Stachnik et al. 2012), but this also requires a good azimuthal distribution of the signals in order to average out anomalies due to structure. Another problem is the naturally high noise level on the horizontal OBS components in combination with the small amplitudes of teleseismic events. A new approach is to use ambient noise instead of teleseismic events (Zha et al. 2013). For this method, virtual Rayleigh waves are calculated from the cross-correlations of vertical and horizontal components of various station pairs. These virtual Rayleigh waves can be used for a similar polarization analysis as that applied to teleseismic data.

Timing

Although the internal clocks in OBS data loggers are synchronized to an external time signal (e.g., GPS) before launching and after retrieving the instrument, the clock can stop before the final synchronization or an incorrect reference time can be recorded during one of the synchronizations. The offset between the internal clock and the external signal after recovery (“skew”) must be corrected, as many applications (e.g., active seismics and event localization) rely on a precise common time base of all stations.

There are two main methods used to correct/verify drift rates in the seismological data, and both procedures assume a constant linear clock drift over the entire recording time. Using the first method, earthquakes or shots are located using data from the OBS, and then the time residuals for each station are plotted as a function of time. A bad timing or non-drift-corrected instrument can be identified by a linear trend in the time residuals. A bad clock drift is often caused by misreading the synchronization time by a multiple of 1 s, so the correction is quite simple to calculate. A non-drift-corrected instrument will have a nonintegral seconds offset at the end of the experiment, allowing a less precise correction.

If several instruments are badly corrected, it can be challenging to determine which one is faulty as several time residuals will exhibit interrelated drift. Ambient noise analysis can also be used to determine the clock drift (Hannemann et al. 2013). Cross-correlations of the vertical seismometer components of station pairs show time shifts if the stations are not properly time corrected. This method also tests the synchronizations and the linearity of the clock drift.

Passive seismological data are normally divided into daily files to keep the huge data amounts manageable. The start time for each daily file is corrected to account for the time drift. Most seismological data formats do not have an accurate enough sample rate specification to account for the drift, which is generally smaller than 1 part in 10^8 (e.g., the true sampling rate for nominally 100 sps data could be 100.000001 sps), so the time at the end of the daily file will be off by the drift rate times the 86,400 s in 1 day. Normally, this offset is smaller than one sample, but this can produce gaps in the data stream. To avoid these gaps, the entire data set can be resampled to a new, skew-corrected sampling rate. Now, the data will be continuous, but the shape of the signal may be slightly changed. Whether resampling is used or not depends on the further usage of the data and analyses to be applied.

Alternatively, some data formats (e.g., miniSEED) allow the time to be specified several times throughout the day. In the miniSEED format, the start time, the time correction, and whether this time correction was applied to the start time can be specified in every record header, which typically occurs every 500–2,000 samples (for a 4,096-byte record length and depending on compression). Although this allows an accurate specification of the clock drift, the software reading the data must still be able to stitch the data together properly when assembling multi-day records. How to do this does not yet appear to have been defined.

Noise Reduction

Noise levels of OBS data are generally higher than of onshore data, because ocean-bottom

seismometers are less coupled to the ground and the oceans are a very noisy environment. At low frequencies (<0.1 Hz), the two major sources of noise are seafloor currents and ocean waves, which have the strongest effect on, respectively, the horizontal channels and the pressure channel. Much of this noise can be removed from the vertical channel by removing the correlated signal on the pressure and horizontal seismometer channels (Webb and Crawford 1999; Crawford and Webb 2000).

The current noise is removed by calculating the transfer functions (the amplitude ratio between the two in the frequency domain) between the horizontal channels and the vertical channel in the absence of earthquakes and then subtracting the horizontal channels times this transfer function from the vertical channel. Next, the transfer function between the pressure channel and the vertical channel is calculated, and the pressure data times this transfer function is subtracted from the vertical channel. If $G_{AA}(f)$ is the power spectral density (mean squared fast Fourier transform (FFT) over several windows) of the channel we want to remove noise from, $G_{SS}(f)$ is the power spectral density of the channel containing the noise source, and $C_{AS}(f)$ is the coherency between them, then the transfer function is defined as

$$T_{AS}(f) = C_{AS}(f) \sqrt{\frac{G_{AA}(f)}{G_{SS}(f)}}$$

The transfer function is then a measure of how much of the noise on the “source” channel is induced into the vertical channel. Channel A is then “cleaned” by calculating its FFT, $A(f)$, and that of the source channel, $S(f)$, applying the formula

$$A'(f) = A(f) - T_{AS}^*(f)S(f)$$

and taking the inverse FFT of $A'(f)$ to get the time domain signal. Note that the power spectral densities and coherence should be calculated on an earthquake-free section of data, so that the only relation between them is the noise to be removed.

If removing the noise recorded on multiple channels, either a multi-coherence method must be used or each channel must be cleaned of the other before being sequentially used to clean the vertical channel. Calling the vertical channel “Z,” the horizontal channels “X” and “Y,” and the pressure channel “P,” the standard sequence is:

1. Calculate Z', Y' and P' by subtracting the coherent part of X.
2. Calculate Z'' and P'' by subtracting the coherent part of Y' .
3. Calculate Z''' by subtracting the coherent part of P'' .

This correction does not distort seismological signals because $T_{ZS}(f) \ll 1$ for the noise sources, whereas $T_{ZS}(f) = O(1)$ for seismological signals. This method cannot be used to improve the horizontal channels, for two reasons. First, the horizontal channel noise is only reduced by a few dB when the correlated noise from the other horizontal channel is removed (compared to 20+ dB for the vertical channel). Second, $T_{XY}(f) = O(1)$ for both the noise and seismological signals, so applying this correction would greatly distort the seismological signal.

These techniques should only be applied at frequencies below the microseism band. In the microseism band, the dominant “noise” signals are seismic surface waves, so removing the correlated pressure or horizontal channel signal would also eliminate, or strongly distort, seismic signals. Removing the horizontal signal times a transfer function from the vertical channel does not significantly alter the shape of any seismic waves that are also recorded on the horizontal, as the seafloor current transfer function is typically on the order of 10^{-3} or less, much smaller than the transfer function for seismic waves.

Summary

Ocean-bottom seismometers are indispensable for exploring offshore structures like mid-ocean ridges, continental margins, hydrocarbon reservoirs, or potential tsunami-generating areas, as

well as “mixed” areas such as hot-spot volcanoes, island chains, and many plate interfaces. Since the first OBS deployments in 1939, technology has advanced rapidly and modern autonomous OBS contain state-of-the art mechanics and electronics. All elements are of a rugged design to cope with the harsh conditions on board and on the sea bottom like high pressure and saltwater environment. An OBS consists of an instrument carrier with floatation made of one or more evacuated glass spheres or syntactic foam and an anchor weight coupled to a release unit. After sinking freely to the seafloor, a seismometer, a hydrophone or an absolute/differential pressure gauge, and a data logger record seismic signals continuously. Receiving a hydroacoustic signal or waiting a prespecified time, the anchor is detached from the instrument and the OBS rises back to the sea surface. Signal color painting, radio beacon, flasher, and a flag facilitate the recovery of the instrument. In contrast to onshore stations, ocean-bottom stations need some additional data processing to enhance the data quality like to orient the seismometer, correction of the drift of the internal clock, and reduction of noise on the vertical component.

Real-time response extrapolation

Introduction

The dynamic forces acting on a structure and the corresponding system response are of great importance to many engineering applications. Often, however, the dynamic forces can hardly be obtained directly by measurements, e.g., for wind loads, and the number of response measurements during operation is in most cases limited due to practical and economical considerations. Therefore, the dynamic forces and corresponding system response have to be determined indirectly from measurements using system inversion techniques. These techniques allow estimating the dynamic forces acting on a structure from the response in a limited number of sensors, while at the same time the system response can be extrapolated to unmeasured locations from the identified forces and system states.

Originally, force identification and state estimation problems were treated separately. Force identification problems were solved offline in a deterministic setting. Many methods were proposed, most of them based on the inversion of the frequency response function (Guillaume et al. 2002; Parloo et al. 2003) or making use of a time-domain approach (Klinkov and Fritzen 2007; Nordström and Nordberg 2002). Several state estimation algorithms have been proposed for linear as well as for nonlinear systems (Wu and Smyth 2007; Hernandez 2011). Currently, the attention is shifted to joint input-state estimation, resulting in numerous recursive combined deterministic-stochastic approaches (Hwang et al. 2009; Ma et al. 2003; Gillijns and De Moor 2007). These methods allow for online response estimation in many engineering fields. This contribution focuses on recursive state estimation and joint input-state estimation algorithms applied for response estimation in structural dynamics.

System Model

In structural dynamics, first principle models, e.g., finite element (FE) models, are widely used. In many cases, modally reduced-order

models are applied, constructed from a limited number of structural modes. When proportional damping is assumed, the continuous-time decoupled equations of motion for modally reduced-order models are given by

$$\ddot{\mathbf{z}}(t) + \mathbf{\Gamma}\dot{\mathbf{z}}(t) + \mathbf{\Omega}^2\mathbf{z}(t) = \mathbf{\Phi}^T\mathbf{S}_p(t)\mathbf{p}(t) \quad (1)$$

where $\mathbf{z}(t) \in \mathbb{R}^{n_m}$ is the vector of modal coordinates, with n_m the number of modes taken into account in the model. The excitation force is written as the product of a selection matrix $\mathbf{S}_p(t) \in \mathbb{R}^{n_{\text{dof}} \times n_p}$, specifying the force locations, and a time history vector $\mathbf{p}(t) \in \mathbb{R}^{n_p}$, with n_{dof} the number of degrees of freedom of the FE model and n_p the number of forces. $\mathbf{\Gamma} \in \mathbb{R}^{n_m \times n_m}$ is a diagonal matrix containing the terms $2\xi_j\omega_j$ on its diagonal, where ω_j and ξ_j are the natural frequency and modal damping ratio corresponding to mode j , respectively. $\mathbf{\Omega} \in \mathbb{R}^{n_m \times n_m}$ is a diagonal matrix as well, containing the natural frequencies ω_j on its diagonal, and $\mathbf{\Phi} \in \mathbb{R}^{n_{\text{dof}} \times n_m}$ is a matrix containing the mass normalized mode shapes $\mathbf{\Phi}_j$ as columns.

The output vector is generally written as

$$\mathbf{d}(t) = \mathbf{S}_{d,a}\mathbf{\Phi}\ddot{\mathbf{z}}(t) + \mathbf{S}_{d,v}\mathbf{\Phi}\dot{\mathbf{z}}(t) + \mathbf{S}_{d,d}\mathbf{\Phi}\mathbf{z}(t) \quad (2)$$

where $\mathbf{S}_{d,a}$, $\mathbf{S}_{d,v}$, and $\mathbf{S}_{d,d} \in \mathbb{R}^{n_d \times n_{\text{dof}}}$ are selection matrices indicating the degrees of freedom corresponding to the acceleration, velocity, and displacement or strain measurements, respectively. The output vector is composed of $n_{d,d}$ displacement or strain measurements, $n_{d,v}$ velocity measurements, and $n_{d,a}$ acceleration measurements, where n_d is the sum of $n_{d,d}$, $n_{d,v}$, and $n_{d,a}$.

Equations 1 and 2 can be written into state-space form. After time discretization and adding noise, the following discrete-time combined deterministic-stochastic state-space description of the system is obtained:

$$\mathbf{x}_{[k+1]} = \mathbf{A}\mathbf{x}_{[k]} + \mathbf{B}\mathbf{p}_{[k]} + \mathbf{w}_{[k]} \quad (3)$$

$$\mathbf{d}_{[k]} = \mathbf{G}\mathbf{x}_{[k]} = \mathbf{J}\mathbf{p}_{[k]} + \mathbf{v}_{[k]} \quad (4)$$

where $\mathbf{x}_{[k]} = \mathbf{x}(k\Delta t)$, $\mathbf{p}_{[k]} = \mathbf{p}(k\Delta t)$, and $\mathbf{d}_{[k]} = \mathbf{d}(k\Delta t)$, $k = 1, \dots, N$, Δt is the sampling

time step, and N is the total number of samples. $\mathbf{d}_{[k]} \in \mathbb{R}^{n_d}$ is the output vector, assumed to be measured, and $\mathbf{p}_{[k]} \in \mathbb{R}^{n_p}$ is the input vector. The state vector $\mathbf{x}_{[k]} \in \mathbb{R}^{2n_m}$ consists of the modal displacements and velocities:

$$\mathbf{x}_{[k]} = \begin{bmatrix} \mathbf{z}_{[k]} \\ \dot{\mathbf{z}}_{[k]} \end{bmatrix} \quad (5)$$

The deterministic system behavior is described by the four system matrices $\mathbf{A}$, $\mathbf{B}$, $\mathbf{G}$, and $\mathbf{J}$. The process noise vector $\mathbf{w}_{[k]} \in \mathbb{R}^{2n_m}$ and measurement noise vector $\mathbf{v}_{[k]} \in \mathbb{R}^{n_d}$ account for unknown excitation sources and modeling errors. In addition, the measurement noise vector $\mathbf{v}_{[k]}$ accounts for measurement errors. As an alternative to models based on first principles, models can be directly identified from experimental vibration data using system identification techniques; see, e.g., Van Overschee and De Moor (1993) and Reynders and De Roeck (2008).

State Estimation

The objective of state estimation is to estimate the system states from a limited number of response measurements (e.g., acceleration measurements) and a system model. The state vector can be determined using a deterministic approach (e.g., least squares estimation of the state vector in the frequency domain) or using a combined deterministic-stochastic approach, which mostly results in recursive time-domain algorithms which can be applied for online state estimation. The best-known recursive state estimation algorithm for linear systems is the Kalman filter algorithm (Kalman 1960), which is outlined next.

In the derivation of the Kalman filter, the unknown system input is assumed to be zero-mean white noise and is included in the vectors $\mathbf{w}_{[k]}$ and $\mathbf{v}_{[k]}$. Under this assumption, the system described by Eqs. 3 and 4 becomes

$$\mathbf{x}_{[k+1]} = \mathbf{A}\mathbf{x}_{[k]} + \mathbf{w}_{[k]} \quad (6)$$

$$\mathbf{d}_{[k]} = \mathbf{G}\mathbf{x}_{[k]} + \mathbf{v}_{[k]} \quad (7)$$

The noise processes $\mathbf{w}_{[k]}$ and $\mathbf{v}_{[k]}$, which now account for all excitation sources, are assumed to be zero mean and white, with known covariance matrices $\mathbf{Q}$, $\mathbf{R}$, and $\mathbf{S}$:

$$\mathbb{E} \left[\begin{pmatrix} \mathbf{w}_{[k]} \\ \mathbf{v}_{[k]} \end{pmatrix} \begin{pmatrix} \mathbf{w}_{[l]}^T & \mathbf{v}_{[l]}^T \end{pmatrix} \right] = \begin{bmatrix} \mathbf{Q} & \mathbf{S} \\ \mathbf{S}^T & \mathbf{R} \end{bmatrix} \delta_{[k-l]} \quad (8)$$

with $\mathbf{R} > 0$, $\begin{bmatrix} \mathbf{Q} & \mathbf{S} \\ \mathbf{S}^T & \mathbf{R} \end{bmatrix} \geq 0$, and $\delta_{[k]} = 1$ for $k = 0$ and 0 otherwise.

If the covariance matrix of the unknown system input $\mathbf{C}_p \in \mathbb{R}^{n_{\text{dof}} \times n_{\text{dof}}}$ and the measurement error covariance matrix $\mathbf{R}_m \in \mathbb{R}^{n_d \times n_d}$ are known, the noise covariance matrices are calculated as

$$\begin{bmatrix} \mathbf{Q} & \mathbf{S} \\ \mathbf{S}^T & \mathbf{R} \end{bmatrix} = \begin{bmatrix} \mathbf{B}_{\text{dof}} \\ \mathbf{J}_{\text{dof}} \end{bmatrix} \mathbf{C}_p \begin{bmatrix} \mathbf{B}_{\text{dof}}^T & \mathbf{J}_{\text{dof}}^T \end{bmatrix} + \begin{bmatrix} \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{R}_m \end{bmatrix} \quad (9)$$

where the system matrices $\mathbf{B}_{\text{dof}} \in \mathbb{R}^{2n_m \times n_{\text{dof}}}$ and $\mathbf{J}_{\text{dof}} \in \mathbb{R}^{n_d \times n_{\text{dof}}}$ are obtained by assuming $n_p = n_{\text{dof}}$ in Eqs. 3 and 4, respectively, i.e., excitation acting at every degree of freedom in the model.

State estimation consists of estimating the system states $\mathbf{x}_{[k]}$ from a set of response measurements $\mathbf{d}_{[k]}$. A state estimate $\hat{\mathbf{x}}_{[k,l]}$ is defined as an estimate of $\mathbf{x}_{[k]}$, given the output sequence $\mathbf{d}_{[k]}$, with $n = 0, 1, \dots, l$. The corresponding error covariance matrix, denoted as $\mathbf{P}_{[kl]}$, is defined as

$$\mathbf{P}_{[kl]} = \mathbb{E} \left\{ (\mathbf{x}_{[k]} - \hat{\mathbf{x}}_{[k|k-l]}) (\mathbf{x}_{[k]} - \hat{\mathbf{x}}_{[k|k-l]})^T \right\} \quad (10)$$

The Kalman filter algorithm is initialized using an initial state estimate vector $\hat{\mathbf{x}}_{[0|-1]}$ and its error covariance matrix $\mathbf{P}_{[0|-1]}$, both assumed known. Hereafter, it propagates by computing state estimates $\hat{\mathbf{x}}_{[k+1|k]}$ recursively from the following equation:

$$\hat{\mathbf{x}}_{[k+1|k]} = \mathbf{A}\hat{\mathbf{x}}_{[k|k-1]} + \mathbf{K}_{[k]} (\mathbf{d}_{[k]} - \mathbf{G}\hat{\mathbf{x}}_{[k|k-1]}) \quad (11)$$

The gain matrix $\mathbf{K}_{[k]}$ is determined such that the state estimates are minimum variance

and unbiased (i.e., $\mathbf{K}_{[k]} = \operatorname{argmin}_{\mathbf{K}_{[k]}} \operatorname{tr}\{\mathbf{P}_{[k|k]}\}$, $\mathbb{E}\{\mathbf{x}_{[k]} - \hat{\mathbf{x}}_{[k|k-1]}\} = \mathbf{0}$). The recursive state estimator of the form (11) can be split in two steps, i.e., the measurement update and the time update:

Measurement update

$$\mathbf{L}_{[k]} = \mathbf{P}_{[k|k-1]} \mathbf{G}^T (\mathbf{G} \mathbf{P}_{[k|k-1]} \mathbf{G}^T + \mathbf{R})^{-1} \quad (12)$$

$$\hat{\mathbf{x}}_{[k|k]} = \hat{\mathbf{x}}_{[k|k-1]} + \mathbf{L}_{[k]} (\mathbf{d}_{[k]} - \mathbf{G} \hat{\mathbf{x}}_{[k|k-1]}) \quad (13)$$

$$\mathbf{P}_{[k|k]} = \mathbf{P}_{[k|k-1]} - \mathbf{P}_{[k|k-1]} \mathbf{G}^T (\mathbf{G} \mathbf{P}_{[k|k-1]} \mathbf{G}^T + \mathbf{R})^{-1} \mathbf{G} \mathbf{P}_{[k|k-1]} \quad (14)$$

with $\mathbf{K}_{[k]} = \mathbf{A} \mathbf{L}_{[k]}$

Time update

$$\hat{\mathbf{x}}_{[k+1|k]} = \mathbf{A} \hat{\mathbf{x}}_{[k|k]} \quad (15)$$

$$\mathbf{P}_{[k+1|k]} = \mathbf{A} \mathbf{P}_{[k|k]} \mathbf{A}^T + \mathbf{Q} - \mathbf{A} \mathbf{L}_{[k]} \mathbf{S}^T - \mathbf{S} \mathbf{L}_{[k]}^T \mathbf{A}^T \quad (16)$$

The algorithm given in Eqs. 12, 13, 14, 15, and 16 distinguishes itself from the classical Kalman filter by including the correlation between the process noise vector $\mathbf{w}_{[k]}$ and the measurement noise vector $\mathbf{v}_{[k]}$, i.e., $\mathbf{S} \neq \mathbf{0}$. In the equations above, the system is assumed to be time invariant. The algorithm can, however, also be applied to time-variant systems, resulting in system matrices $\mathbf{A}_{[k]}$ and $\mathbf{G}_{[k]}$ depending on the time step k .

In general, the system input does not satisfy the white noise assumption. The Kalman filter, however, yields good results as long as the applied forces are broadband and approximately white. If the forces acting to the structure do not meet this assumption, the quality of the estimated states can be improved by estimating both the system input and states, i.e., joint input-state estimation.

Joint Input-State Estimation

The objective of joint input-state estimation is to jointly estimate the forces applied to the system and the corresponding states from a limited

number of response measurements and a system model. Similar to state estimation, the applied forces can be determined using a deterministic approach, e.g., Guillaume et al. (2002), or alternatively using a combined deterministic-stochastic approach, which mostly results in recursive time-domain algorithms which can be applied for online joint input-state estimation. The algorithm outlined next is a joint input-state estimation algorithm which was originally proposed by Gillijns and De Moor (2007). The algorithm was applied for force identification and response estimation in structural dynamics by Lourens et al. (2012) and was extended for applications in structural dynamics where ambient excitation becomes important by Maes et al. (2013).

The system under consideration is described by Eqs. 3 and 4. The noise processes $\mathbf{w}_{[k]}$ and $\mathbf{v}_{[k]}$ are assumed to be zero mean and white, with known covariance matrices $\mathbf{Q}$, $\mathbf{R}$, and $\mathbf{S}$, defined by Eq. 8. Joint input-state estimation consists of estimating the forces $\mathbf{p}_{[k]}$ and states $\mathbf{x}_{[k]}$ from a set of response measurements $\mathbf{d}_{[k]}$. A state estimate $\hat{\mathbf{x}}_{[k|l]}$ is defined as an estimate of $\mathbf{x}_{[k]}$, given the output sequence $\mathbf{d}_{[n]}$, with $n = 0, 1, \dots, l$. The corresponding error covariance matrix, denoted as $\mathbf{P}_{[k|l]}$, is defined in Eq. 10. An input estimate $\hat{\mathbf{p}}_{[k|l]}$ and its error covariance matrix $\mathbf{P}_{p[k|l]}$ are defined similarly. The filtering algorithm is initialized using an initial state estimate vector $\hat{\mathbf{x}}_{[0|-1]}$ and its error covariance matrix $\mathbf{P}_{[0|-1]}$, both assumed known. Hereafter, it propagates by computing the force and state estimates recursively in three steps, i.e., the input estimation step, the measurement update, and the time update:

Input estimation

$$\tilde{\mathbf{R}}_{[k]} = \mathbf{G} \mathbf{P}_{[k|k-1]} \mathbf{G}^T + \mathbf{R} \quad (17)$$

$$\mathbf{M}_{[k]} = \left(\mathbf{J}^T \tilde{\mathbf{R}}_{[k]}^{-1} \mathbf{J} \right)^{-1} \mathbf{J}^T \tilde{\mathbf{R}}_{[k]}^{-1} \quad (18)$$

$$\hat{\mathbf{p}}_{[k|k]} = \mathbf{M}_{[k]} (\mathbf{d}_{[k]} - \mathbf{G} \hat{\mathbf{x}}_{[k|k-1]}) \quad (19)$$

$$\mathbf{P}_{p[k|k]} = \left(\mathbf{J}^T \tilde{\mathbf{R}}_{[k]}^{-1} \mathbf{J} \right)^{-1} \quad (20)$$

Measurement update

$$\mathbf{L}_{[k]} = \mathbf{P}_{[k|k-1]} \mathbf{G}^T \tilde{\mathbf{R}}_{[k]}^{-1} \quad (21)$$

$$\hat{\mathbf{x}}_{[k|k]} = \hat{\mathbf{x}}_{[k|k-1]} + \mathbf{L}_{[k]} \left(\mathbf{d}_{[k]} - \mathbf{G} \hat{\mathbf{x}}_{[k|k-1]} - \mathbf{J} \hat{\mathbf{p}}_{[k|k]} \right) \quad (22)$$

$$\mathbf{P}_{[k|k]} = \mathbf{P}_{[k|k-1]} + \mathbf{L}_{[k]} \left(\tilde{\mathbf{R}}_{[k]} - \mathbf{J} \mathbf{P}_{[k|k]} \mathbf{J}^T \right) \mathbf{L}_{[k]}^T \quad (23)$$

$$\mathbf{P}_{xp[k|k]} = \mathbf{P}_{px[k|k]}^T - \mathbf{L}_{[k]} \mathbf{J} \mathbf{P}_{[k|k]} \quad (24)$$

Time update

$$\hat{\mathbf{x}}_{[k+1|k]} = \mathbf{A} \hat{\mathbf{x}}_{[k|k]} + \mathbf{B} \hat{\mathbf{p}}_{[k|k]} \quad (25)$$

$$\mathbf{N}_{[k]} = \mathbf{A} \mathbf{L}_{[k]} (\mathbf{I} - \mathbf{J} \mathbf{M}_{[k]}) + \mathbf{B} \mathbf{M}_{[k]} \quad (26)$$

$$\begin{aligned} \mathbf{P}_{[k+1|k]} = & \begin{bmatrix} \mathbf{A} & \mathbf{B} \end{bmatrix} \begin{bmatrix} \mathbf{P}_{[k|k]} & \mathbf{P}_{xp[k|k]} \\ \mathbf{P}_{px[k|k]} & \mathbf{P}_{[k|k]} \end{bmatrix} \begin{bmatrix} \mathbf{A}^T \\ \mathbf{B}^T \end{bmatrix} \\ & + \mathbf{Q} - \mathbf{N}_{[k]} \mathbf{S}^T - \mathbf{S} \mathbf{N}_{[k]}^T \end{aligned} \quad (27)$$

The gain matrices $\mathbf{M}_{[k]}$ and $\mathbf{L}_{[k]}$ are determined such that both the input estimates $\hat{\mathbf{p}}_{[k|k]}$ and the state estimates $\hat{\mathbf{x}}_{[k|k-1]}$ are minimum variance and unbiased (i.e., $\mathbf{M}_{[k]} = \operatorname{argmin}_{\mathbf{M}_{[k]}} \operatorname{tr} \{ \mathbf{P}_{p[k|k]} \}$, $\mathbb{E} \{ \mathbf{p}_{[k]} - \hat{\mathbf{p}}_{[k|k]} \} = 0$, $\mathbf{L}_{[k]} = \operatorname{argmin}_{\mathbf{L}_{[k]}} \operatorname{tr} \{ \mathbf{P}_{[k|k]} \}$, and $\mathbb{E} \{ \mathbf{x}_{[k]} - \hat{\mathbf{x}}_{[k|k]} \} = 0$). In the equations above, the system is assumed to be time invariant. The algorithm can, however, also be applied to time-variant systems, resulting in system matrices $\mathbf{A}_{[k]}$, $\mathbf{B}_{[k]}$, $\mathbf{G}_{[k]}$, and $\mathbf{J}_{[k]}$ depending on the time step k .

Very often unknown ambient forces such as wind loads are acting on the structure. For these loads, the force locations or spatial distributions of the forces are not well known. In this case, the estimated forces $\mathbf{p}_{[k]}$ compensate for any unknown source of vibration. They are not the true forces acting on the structure but equivalent forces that act at predefined locations (Lourens et al. 2012).

Response Estimation

After applying the Kalman filter algorithm or the joint input-state estimation algorithm, the estimated state vector $\hat{\mathbf{x}}_{[k|k]}$ and force vector $\hat{\mathbf{p}}_{[k|k]}$ (in the case of joint input-state estimation) can be used to estimate the output at any arbitrary location in the structure, using the following modified output equation:

$$\hat{\mathbf{d}}_{e[k|k]} = \mathbf{G}_e \hat{\mathbf{x}}_{[k|k]} + \mathbf{J}_e \hat{\mathbf{p}}_{[k|k]} \quad (28)$$

where $\hat{\mathbf{d}}_{e[k|k]}$ is the estimated response. The matrices $\mathbf{G}_e$ and $\mathbf{J}_e$ are related to the extrapolated output quantities $\hat{\mathbf{d}}_{e[k|k]}$ and, therefore, do not equal the original matrices $\mathbf{G}$ and $\mathbf{J}$. Note that when Eq. 28 is used after applying the Kalman filter algorithm, the excitation $\hat{\mathbf{p}}_{[k|k]}$ is contained in the noise vectors $\mathbf{w}_{[k]}$ and $\mathbf{v}_{[k]}$ (cf. Eq. 7) and therefore disregarded. In this way, an error is introduced for acceleration estimation. For displacement, velocity, or strain estimation, this is not the case, as there is no direct feedthrough from the ambient forces $\hat{\mathbf{p}}_{[k|k]}$ to the output $\hat{\mathbf{d}}_{e[k|k]}$ which has to be accounted for (i.e., the rows of the matrix $\mathbf{J}_e$ corresponding to the displacement, velocity, or strain measurements are all zero).

Application: Response Estimation in a Three-Story Shear Building Subject to an Earthquake

The response estimation procedure is illustrated using numerical simulations for a three-story building subjected to horizontal earthquake excitation. The building is modeled as an idealized shear building (Fig. 1). The story masses are lumped to the floor levels, the floors are presumed infinitely rigid, and axial member deformations are neglected. This system is described by three degrees of freedom (DOFs), u_1 , u_2 , and u_3 . Under the assumption that the structure is subjected to a uniform horizontal base motion $\ddot{u}_g(t)$, the system is governed by the following set of equations of motion:

Online Response Estimation in Structural Dynamics, Fig. 1 A three-story shear building model and its mass, damping, and stiffness matrices

$$\mathbf{M}\ddot{\mathbf{u}}(t) + \mathbf{C}\dot{\mathbf{u}}(t) + \mathbf{K}\mathbf{u}(t) = \mathbf{S}_p(t)\mathbf{p}(t) \quad (29)$$

where $\mathbf{u}(t) = [u_1(t), u_2(t), u_3(t)]^T$ is the vector of displacements relative to the displacements of the building basement and $\mathbf{M}$, $\mathbf{C}$, and $\mathbf{K}$ are the mass, damping, and stiffness matrix of the

structure, respectively, defined in Fig. 1. $\mathbf{S}_p(t) = \mathbf{I}_3$ and $\mathbf{p}(t) = [-m_1, -m_2, -m_3]^T \ddot{u}_g(t)$, where $\mathbf{I}_3 \in \mathbb{R}^{3 \times 3}$ is an identity matrix.

The story masses m_i , damping values c_i , and stiffnesses k_i are assumed known and are given by

$$\begin{array}{lll} m_1 = 10 \times 10^3 \text{ kg} & c_1 = 6 \times 10^3 \text{ Ns/m} & k_1 = 6 \times 10^6 \text{ N/m} \\ m_2 = 10 \times 10^3 \text{ kg} & c_2 = 7 \times 10^3 \text{ Ns/m} & k_2 = 7 \times 10^6 \text{ N/m} \\ m_3 = 10 \times 10^3 \text{ kg} & c_3 = 8 \times 10^3 \text{ Ns/m} & k_3 = 8 \times 10^6 \text{ N/m} \end{array} \quad (30)$$

The modal properties of the system are found as the solution of the undamped eigenvalue equation $\mathbf{K}\Phi = \mathbf{M}\Phi\Lambda$, where $\Phi \in \mathbb{R}^{3 \times 3}$ collects the three eigenvectors $\phi_j \in \mathbb{R}^3$ that correspond to the eigenvalues $\lambda_j = \omega_j^2 = (2\pi f_j)^2$ located on the diagonal of Λ . The first three natural frequencies f_j of the shear building are found as 2.72, 7.27, and 10.59 Hz. The corresponding mode shapes are shown in Fig. 2. The modal damping ratios ξ_j are calculated as $\gamma_j/(2\omega_j)$, where γ_j is a diagonal element of the matrix Γ , with $\Gamma = \Phi^T \mathbf{C} \Phi$. Note that $\mathbf{C} = 10^{-3} \text{ s} \times \mathbf{K}$, so proportional damping was implicitly assumed. The first three modal damping ratios of the shear building are 0.85 %, 2.28 %, and 3.33 %.

The building is subject to the horizontal ground motion recorded during the Northridge earthquake that occurred on January 17, 1994. The epicenter of the earthquake was located in Northridge, California. The ground motion considered was recorded in the

northwest direction in Montebello, California (http://peer.berkeley.edu/peer_ground_motion_database). The time history and narrowband frequency spectrum of the recorded ground acceleration $\ddot{u}_g$ are shown in Fig. 3.

A reduced-order state-space model is constructed from the first three eigenmodes of the shear building, applying a zero-order hold assumption on the force. The data assumed for the response estimation consists of the ground acceleration time history $\ddot{u}_g$, three absolute horizontal acceleration time histories, $\ddot{u}_{a,1}$, $\ddot{u}_{a,2}$, and $\ddot{u}_{a,3}$, and one relative horizontal displacement time history, u_3 . The response is calculated at a sampling rate of 100 Hz. The initial state $\mathbf{x}_{[0]}$ is assumed zero. The output vector $\mathbf{d}_{[k]}$ considered for response estimation is composed of the relative acceleration time histories $\ddot{u}_1$, $\ddot{u}_2$, and $\ddot{u}_3$ and the relative displacement time history u_3 , where $\ddot{u}_j = \ddot{u}_{a,j} - \ddot{u}_g$. Note that the ground acceleration time history $\ddot{u}_g$ can also be used directly as input

Online Response Estimation in Structural Dynamics, Fig. 2 Three natural modes of the three-story shear building

Online Response Estimation in Structural Dynamics, Fig. 3 (a) Time history and (b) narrowband frequency spectrum up to 15 Hz of the recorded ground accelerations

in northwest direction due to the Northridge earthquake, January 17, 1994, 12:31 UTC, Montebello, California

to a forward calculation, hereby obtaining the response in the structure at predefined locations. The proposed filtering algorithms, however, have the advantage of canceling out measurement errors and modeling errors. A small error on the natural frequencies of the system, for example, hardly influences the quality of the predicted response obtained by applying the Kalman filter or the joint input-state estimation algorithm, whereas for the forward calculation, this is mostly not the case.

Gaussian white noise is added to the ground acceleration time history $\ddot{u}_g$ and to the calculated time histories ($\ddot{u}_{a,1}$, $\ddot{u}_{g,2}$, $\ddot{u}_{a,3}$, and u_3), in order to represent the measurement error on the data. A choice is made to assume the same noise level γ_a for all acceleration signals and a noise

level γ_d for the displacement signal. The noise level γ_a is 5 % of the maximal acceleration $\ddot{u}_{a,3}$, and the noise level γ_d is 5 % of the maximal displacement u_3 ($\gamma_a = 0.17 \text{ m/s}^2$, $\gamma_d = 0.54 \text{ mm}$). The polluted output time histories ($\tilde{u}_{1[k]}$, $\tilde{u}_{2[k]}$, $\tilde{u}_{3[k]}$, and $\tilde{u}_{3[k]}$) are calculated according to Eq. 31:

$$\begin{aligned}
 \tilde{u}_{1[k]} &= \ddot{u}_{a,1[k]} - \ddot{u}_g[k] + \gamma_a(r_{a,1[k]} + r_{g[k]}) \\
 \tilde{u}_{2[k]} &= \ddot{u}_{a,2[k]} - \ddot{u}_g[k] + \gamma_a(r_{a,2[k]} + r_{g[k]}) \\
 \tilde{u}_{3[k]} &= \ddot{u}_{a,3[k]} - \ddot{u}_g[k] + \gamma_a(r_{a,3[k]} + r_{g[k]}) \\
 \tilde{u}_{3[k]} &= u_{3[k]} + \gamma_d r_{d,3[k]}
 \end{aligned} \quad (31)$$

where $r_{a,1[k]}$, $r_{a,2[k]}$, $r_{a,3[k]}$, $r_{g[k]}$, and $r_{d,3[k]}$ are random numbers drawn independently from a normal distribution with zero mean and unit

Online Response Estimation in Structural Dynamics, Fig. 5 (a) Time history and (b) narrowband frequency spectrum up to 15 Hz of the simulated displacement $\ddot{u}_3$, measurement noise included

standard deviation. The time history and narrowband frequency spectrum of the simulated acceleration $\ddot{u}_1$ and the displacement $\ddot{u}_3$ are shown in Figs. 4 and 5, respectively.

The response signals are now used as input to the response estimation procedure, hereby comparing the Kalman filter and the joint input-state estimation algorithm presented in sections “[State Estimation](#)” and “[Joint Input-State Estimation](#),” respectively. The response to be estimated consists of the horizontal displacement u_1 of the top floor.

The Kalman filter is applied to estimate the system states $\hat{\mathbf{x}}_{[k|k]}$, and, subsequently, the response of the top floor $\hat{\mathbf{d}}_{e[k|k]}$ is estimated according to Eq. 28, where the term $\mathbf{J}_e \hat{\mathbf{p}}_{[k|k]}$ is disregarded. The noise covariance matrices $\mathbf{Q}$, $\mathbf{R}$, and $\mathbf{S}$ are calculated from Eq. 9, for $\mathbf{C}_p$ and $\mathbf{R}_m$ given by the following equations:

$$\mathbf{C}_p = \begin{bmatrix} m_1^2 & m_1 m_2 & m_1 m_3 \\ m_2 m_1 & m_2^2 & m_2 m_3 \\ m_3 m_1 & m_3 m_2 & m_3^2 \end{bmatrix} \sigma_{\ddot{u}_g}^2 \quad (32)$$

$$\mathbf{R}_m = \begin{bmatrix} 2\gamma_a^2 & \gamma_a^2 & \gamma_a^2 & 0 \\ \gamma_a^2 & 2\gamma_a^2 & \gamma_a^2 & 0 \\ \gamma_a^2 & \gamma_a^2 & 2\gamma_a^2 & 0 \\ 0 & 0 & 0 & \gamma_d^2 \end{bmatrix} \quad (33)$$

where $\sigma_{\ddot{u}_g}$ is the standard deviation of the ground acceleration $\ddot{u}_g$ imposed to the building, assumed 0.2 m/s² for this example. The initial state estimate vector $\hat{\mathbf{x}}_{[0|-1]}$ and its error covariance matrix $\mathbf{P}_{[0|-1]}$ are both assumed zero.

The joint input-state estimation algorithm is applied to estimate the system states $\hat{\mathbf{x}}_{[k|k]}$ and the applied forces $\hat{\mathbf{p}}_{[k|k]}$, hereafter estimating the response of the top floor $\hat{\mathbf{d}}_{e[k|k]}$, according to Eq. 28. A distribution of the equivalent force is

Online Response Estimation in Structural Dynamics, Fig. 6 (a) Complete and (b) detail of the simulated (gray) and estimated displacement time history u_1 (red, Kalman filter; blue, joint input-state estimation algorithm)

assumed by putting $\mathbf{S}_p(t) = [1, m_2/m_1, m_3/m_1]^T$ in Eq. 29. The estimated force $\hat{\mathbf{p}}_{[k|k]} \in \mathbb{R}$ has a physical meaning, i.e., the inertial force resulting from the ground motion applied at the top of the shear building. The noise covariance matrices $\mathbf{Q}$, $\mathbf{R}$, and $\mathbf{S}$ are calculated from Eq. 9, for $\mathbf{C}_p = \mathbf{0}$ and $\mathbf{R}_m$ given by Eq. 33. The initial state estimate vector $\hat{\mathbf{x}}_{[0|-1]}$ and its error covariance matrix $\mathbf{P}_{[0|-1]}$ are both assumed zero.

The results of the response estimation procedure are shown in Fig. 6. The detail in Fig. 6b reveals that the results obtained by applying the joint input-state estimation algorithm are more accurate than the results from the Kalman filter. The inertial forces applied to the structure, which result from ground motion, do not perfectly fulfill the white noise assumption, which explains the errors on the results from the Kalman filter. The equivalent forces assumed when applying the joint input-state estimation algorithm successfully compensate for the excitation applied to the structure. As a result, only very small errors on the estimated displacement due to measurement errors remain.

Summary

This reference entry focuses on two recursive time-domain algorithms that can be applied for response estimation in structural dynamics. The first algorithm is the Kalman filter, a well-known state estimation algorithm that has been used for many applications in various engineering

disciplines. The second algorithm is a recursive joint input-state estimation algorithm. Both algorithms are briefly outlined and thereafter compared using simulations for a three-story building subject to an earthquake.

Operational Modal Analysis in Civil Engineering: An Overview

Edwin Reynders and Guido De Roeck
Department of Civil Engineering, KU Leuven,
Leuven, Belgium

Synonyms

Ambient vibration testing; System identification

Introduction

The susceptibility of civil structures and buildings to vibrations is the major concern when designing earthquake-resistant structures. The experimental verification of the dynamic design

values, in particular the relevant standing wave or modal characteristics (natural frequencies, damping ratios, and mode shapes), is essential for validating the dynamic structural design, hence for guaranteeing the safety of the structure under earthquake loading. Furthermore, the modal characteristics depend on the stiffness of the structure, so monitoring their evolution over time allows, in principle, to identify structural damage. For example, comparing modal characteristics that have been measured before and after the occurrence of an earthquake can help in detecting structural damage that is not directly visible. However, modal characteristics may also be sensitive to environmental conditions, such as temperature or relative humidity, and to loading conditions such as excitation amplitude or added mass. These influences need to be properly taken into account when employing the results of a modal test for design validation, model calibration, structural health monitoring, etc.

Depending on the type of excitation that is employed to perform a modal test, a distinction is made between forced vibration testing, ambient vibration testing, and combined or hybrid vibration testing, also termed experimental modal analysis (EMA), operational modal analysis (OMA), and operational modal analysis with exogenous inputs (OMAX), respectively. In EMA, which was historically the first testing approach that was developed, the structure is excited by one or several measured dynamic forces, the response of the structure to these forces is recorded, and the modal characteristics in the frequency range of interest are identified from the measured data. The first EMA techniques were single degree of freedom methods such as peak picking and circle fitting, in which it is assumed that at resonance, only a single mode dominates. Consequently, these techniques are not useful when some modes of interest have close natural frequencies. This disadvantage was later removed with the introduction of multiple degree of freedom methods for EMA. By now, EMA is a well-established and often-used approach in mechanical and aerospace engineering, as documented by,

e.g., Maia and Silva (1997), Heylen et al. (1997), Allemang (1999), and Ewins (2000).

EMA methods are in general not well suited for the modal testing of civil structures and buildings, because these structures cannot be tested in laboratory conditions. When employing compact and practical actuators, the contribution of the measured excitation to the total structural response is rather low. This implies that the ever-present ambient or operational excitation – due to wind or traffic loading, for example – can most often not be neglected. OMA techniques have therefore been developed. They extract the modal characteristics from the measured operational response only. The unmeasured, ambient forces are usually modeled as white noise sequences, i.e., as zero-mean time sequences of which all samples are statistically uncorrelated and have the same variance. In civil engineering, OMA has become the primary modal testing method, especially for structures whose performance under earthquake loading is critical, such as bridges, high-rise buildings, and dams. Peeters and De Roeck (2001) review some established OMA techniques, while Magalhaes and Cunha (2011) provide an extensive tutorial introduction to OMA using bridge vibration data.

Nevertheless, the OMA approach has two disadvantages: the mode shapes cannot be scaled in an absolute way (e.g., mass normalized), and there is no control over the ambient excitation signal, which may be narrow banded in the frequency domain. For these reasons, there has been an increasing interest during the last few years toward combined modal testing or OMAX techniques. The main difference between OMAX and the traditional EMA approach is that the operational loads are included in the identified system model: they are not considered as noise but as useful excitation. Consequently, the amplitude of the artificial forces can be equal to, or even lower than, the amplitude of the operational forces. This is of crucial importance for the modal testing of large structures, since it allows using actuators that are small and practical when compared to the ones needed for EMA testing of such structures. Reynders (2012) provides an in-depth review of the most relevant and powerful EMA, OMA, and

OMAX techniques and compares their performance in an extensive simulation study.

Whether an EMA, OMA, or OMAX approach is followed, all modal tests consist of three distinct stages:

1. Designing the experiment and collecting the vibration response data (for OMA) or the force and vibration response data (for EMA or OMAX)
2. Identifying a set of dynamic structural models belonging to a given model class (e.g., linear time-invariant (LTI)) from the measured data
3. Extracting and validating a set of modal characteristics based on the identified models

Each of these stages is discussed in more detail in the following sections.

Experiment Design and Data Collection

The first stage of an operational modal analysis consists of designing the experiment and gathering the necessary data. For a pure OMA test, only response data are measured. For an OMAX test, the artificial excitation is also measured.

Modes are standing waves. The largest frequency and the shortest wavelength of all standing waves of interest have a prime influence on the experiment design. The largest frequency of interest determines the sampling rate and the necessary synchronization accuracy among the different sensors, which is especially important for wireless sensor networks. Components of the signal with a frequency that is larger than half of the sampling frequency should be filtered out before sampling in order to avoid aliasing. The shortest wavelength of interest determines the spatial resolution of the test: the shorter the wavelength, the closer the response sensors need to be in order to capture the short-wavelength mode shapes in sufficient detail.

For measuring the response of the structure, many types of sensor are available. Figure 1 provides a few examples. Sensor types that are often used include accelerometers which measure uniaxial or triaxial acceleration, velocity or

Operational Modal Analysis in Civil Engineering: An Overview, Fig. 1 Some sensors that are employed for operational modal analysis: two uniaxial wired accelerometers (*left*), a triaxial wireless accelerometer (*middle*), and two optical fiber sensors (*right*) (Right photo

reproduced with permission from: Reynders et al., Damage identification on the Tilff bridge by vibration monitoring using optical fibre strain sensors, *ASCE Journal of Engineering Mechanics*, 133(2):185–193, 2007)

displacement sensors such as laser vibrometers, LVDTs (linear variable differential transformers) and capacitive sensors, and strain sensors such as strain gages or fiber optic sensors. Most sensors only measure at a single location. Some quasi-distributed sensing techniques, based on, e.g., laser scanning or photogrammetry, are available, but their use on large and/or complex structures can be challenging. The development of wireless sensing technology has greatly improved the ease and speed of occasional modal testing.

The number of sensors employed in a test can be smaller than the total number of locations at which the response needs to be measured. In such case, the test is performed in different setups, each of which yields partial mode shape estimates. They can be assembled when sensor locations overlap between different setups in such a way that there is at least one common nonzero modal displacement among both setups for every mode of interest.

For OMAX testing (and also for traditional EMA testing), actuators are also needed. Figure 2 provides a few examples. Whenever the cost of testing and the ease of installation are a concern, the use of shakers can be excluded since they are not very cost-effective. Due to the low maximum force, the classic impact hammer is only feasible for the testing of relatively small structures. A larger and more controllable version consists of a drop weight system. When specific excitation signals are needed (multisine, swept sine, etc.), pneumatic artificial muscles can in some cases provide a good alternative for shakers (Deckers et al. 2008).

When an a priori estimate of the modal characteristics that one wishes to measure is available, e.g., from a preliminary finite element model, it is possible to estimate the optimal sensor (and actuator) configuration according to a given performance measure. As shown recently by Papadimitriou and Lombaert (2012), it is

Operational Modal Analysis in Civil Engineering: An Overview, Fig. 2 Some actuators that are employed for OMAX testing: drop weight system (*left*), impact hammer (*center*), and pneumatic artificial muscle (*right*)

(Reproduced with permission from: Reynders et al., combined experimental-operational modal testing of footbridges, *ASCE Journal of Engineering Mechanics*, 136(6):687–696, 2010)

important to take the effect of spatially correlated prediction errors into account when computing the optimal sensor placement.

System Identification

Once the data have been gathered, a mathematical model that compactly describes the measured signals can be identified. Since the modal characteristics are classically defined as the eigenparameters of a dynamic, linear time-invariant (LTI) system description with general viscous damping, it is such a description that is identified from the OMA or OMAX data (Fig. 3). A very large number of system identification algorithms are available from the literature, but, as shown by Ljung (1999), they can be considered as particular implementations of just a few general ideas. This section therefore provides a concise overview of the different approaches rather than providing a complete list of algorithms. Most identification methods can be applied to time-domain as well as to frequency-domain data. This means that most time-domain system identification algorithms have a

frequency-domain counterpart which often differs from it only by Fourier transforms, and vice versa.

First, a distinction can be made between non-parametric and parametric identification. Non-parametric system identification involves the estimation of an impulse response function, frequency response function (FRF), correlation function, or power spectral density (PSD), not as a mathematical function depending on a few parameters, but as a set of tabulated values for each considered time lag or frequency. Although nonparametric models are sometimes directly used for modal analysis, they are most often used as preprocessed data for parametric identification since the estimation accuracy of parametric approaches is much higher than that of nonparametric approaches (Peeters and De Roeck 2001; Reynders 2012).

Parametric linear system identification as a research discipline originated in the late 1960s and developed along two lines that are still dominant today. The first line is the prediction error framework, where a system model is identified by minimizing the difference between the measured system response and the response predicted by

Operational Modal Analysis in Civil Engineering: An Overview, Fig. 3 A linear time-invariant (*LTI*) system model is identified from measured data. The total response y is measured, and part of the excitation u^d may also be measured. The operational excitation u^s is not measured. The subscript d stands for deterministic, while the subscript s stands for stochastic

the model, most often using the maximum likelihood (ML) principle (Ljung 1999; Pintelon and Schoukens 2001). The second line seeks at identifying the system model by exploiting the correlation structure (over time) of the measured response signals (and, if relevant, the measured excitation signals). This line started with the seminal work of Ho and Kalman (1966) and Akaike (1974) on system realization, which was later generalized into the so-called subspace approach (Van Overschee and De Moor 1996; Katayama 2005). Both approaches have distinct advantages: maximum likelihood methods have optimal asymptotic statistical properties under fairly general assumptions, while subspace methods are very robust, statistically accurate, and computationally much less demanding.

Estimating and Validating a Set of Modal Characteristics

The modal characteristics corresponding to an identified system description can be obtained by exploiting its eigenstructure, that is, by decomposing the original description in terms of its free vibration solutions.

When the identified system description is nonparametric and consists of, e.g., tabulated frequency response data, rough estimates of the modal characteristics can be obtained when the damping is low. One of the most popular techniques, because of its simplicity and intuitiveness, is peak picking. Under the assumptions

that the modes have low damping and well-separated natural frequencies and that the estimated frequency response functions (in case of input-output measurements) or power spectral densities (in case of output-only measurements) are noiseless and have infinite frequency resolution, the natural frequencies can be obtained as the peaks of the frequency response function or power spectral density. The deflection shapes at those frequencies are estimates of the corresponding mode shapes, which converge to the true mode shapes when the damping goes to zero or the natural frequency spacing goes to infinity. The assumption that the natural frequency spacing is large can be relaxed by extending the peak picking method with singular value decomposition (Shih et al. 1988). The corresponding approach is called complex mode indicator function when applied to FRF data and frequency domain decomposition when applied to PSD data. However, peak picking or its extensions often lead to inaccurate estimates because most of its assumptions are not tenable in practical situations, especially in operational conditions. They are therefore mainly used for the estimation of modal characteristics in the preliminary phase of a modal test, even in laboratory conditions (Ewins 2000, p. 304).

When the identified system description is parametric, e.g., in state-space form, no assumptions – other than that the structure's response can be described with the identified description – are needed for estimating the modal characteristics. The assumed damping model is most often general viscous damping, which contains proportional damping as a special case. This means that the approach can also be used when localized dampers are present and the mode shapes are complex.

When compared to nonparametric methods, parametric system identification methods need at least one additional user-defined integer: the model order, which equals the number of eigenvalues present in the model, hence, in theory, twice the number of natural frequencies. From control theory, several model validation techniques are available for choosing the model order in an automated way, so that the prediction

Operational Modal Analysis in Civil Engineering: An Overview, Fig. 4 Stabilization diagram for one setup of a modal test on a three-span prestressed concrete bridge. The modes that are stable in all setups are shown in Fig. 5

capacity of the identified models is maximized (Ljung 1999). However, in modal testing applications, one is not primarily interested in the prediction capacity of an identified model as such, but rather in the physical relevance of the individual modes that constitute the model. An alternative approach has therefore been developed, based on the empirical observation that in a very large number of modal identification problems, the physical modes of the structure appear at nearly the same eigenfrequency when the model order is over-specified, while other spurious modes do not. In this approach, parametric models are estimated for a wide range of model orders, and the modes corresponding to all these models are plotted in a model order versus natural frequency diagram, called stabilization diagram (Heylen et al. 1997; Allemang 1999). The physical modes then show up as vertical lines in the diagram, and one of the modes of each line can be chosen as a representative of the corresponding physical mode. Figure 4 shows an example of a stabilization diagram, and Fig. 5 presents the corresponding stable modes.

Finally, the obtained set of modes can be validated according to relevant validation criteria. A criterion that is often used is the so-called

modal assurance criterion (MAC) which is the dimensionless correlation coefficient between two mode shapes ϕ_j and ϕ_l :

$$MAC(\phi_j, \phi_l) = \frac{|\phi_j^H \phi_l|^2}{\|\phi_j\|^2 \|\phi_l\|^2},$$

where the subscript H denotes complex conjugate (or Hermitian) transpose, $\|\cdot\|$ denotes amplitude, and $\|\cdot\|$ denotes the Euclidian norm. When the mass of the structure is approximately uniformly distributed and the spatial resolution of the identified mode shapes is sufficiently large, the MAC value between different mode shapes should be zero (Allemang and Brown 1982). When real normal modes are expected, i.e., when proportional damping can be assumed, the modal phase collinearity (MPC) can be used for assessing the quality of the identified mode shapes (Pappa et al. 1992). The MPC value of a real normal mode shape, which is collinear in the complex plane, equals unity, while the MPC value of a complex mode shape is significantly lower than unity. Finally, for some of the most powerful parametric identification methods, the statistical accuracy of the estimated modal

characteristics can be assessed. This is, for instance, the case for the stochastic subspace identification method, for which the complete joint probability distribution of the estimated natural frequencies, damping ratios, and mode shape components is available (Reynders et al. 2008; Reynders 2012).

diagram technique for estimating a final set of modal characteristics. Finally, a range of criteria is available for validating the estimated modal characteristics, from assessing the statistical accuracy of the estimates to assessing the complexity of the mode shapes.

Summary

The identification of modal characteristics from vibration data is very important in earthquake engineering, not only for design validation but also for structural health monitoring. Operational modal analysis, which identifies the modal characteristics from measured response data only, is often the most effective modal testing approach in earthquake engineering. Many system identification algorithms are available for estimating modal characteristics from the measured (force-) response data. Nonparametric algorithms are simple and intuitive, but they often yield inaccurate results. Parametric algorithms lead generally to much more accurate estimates; in particular, subspace identification combines a good statistical accuracy with a low computation cost and a high computational robustness. Since parametric algorithms need the model order as a user-defined integer, they are often combined with the stabilization

Introduction

Earthquakes generally occur in response to tectonic loading of the crust. However, once the crust has reached a state of stress close to frictional equilibrium other processes that affect the crustal stress field, such as the filling of a reservoir or water injection in a borehole, may trigger seismicity. The discovery of large fault scarps in northern Fennoscandia, and their subsequent dating to the end of the latest glaciation, the Weichselian, showed that also the load of an ice sheet can have a significant impact on earthquake occurrence.

As an ice sheet grows the weight of the ice will make the lithosphere subside into the softer

asthenosphere below, a process known as glacial isostatic adjustment (GIA). The load increases both vertical and horizontal stresses in the lithosphere, and additional horizontal stresses develop due to the flexure of the elastic part of the lithosphere. Since variations to the size of the ice sheet takes place on much shorter time scales than asthenospheric flow, the flexural stresses develop at a slower pace. How these glacially-induced stresses affect earthquake occurrence depend on the prevailing stress field prior to the start of the glaciation, but generally in continental areas an ice sheet will tend to decrease differential stress under the load and therefore stabilize faults. As the ice retreats the vertical stress will decrease faster than the horizontal flexural stress due to the delayed response of the asthenosphere. In addition, horizontal tectonic stresses may have accumulated under the stabilizing weight of the ice sheet. The combination of deglaciation stresses, accumulated tectonic stress and the pre-existing stress field can potentially destabilize faults and cause large “postglacial” earthquakes, as was the case in Fennoscandia approximately 10,000 years ago.

Since the discovery of the Fennoscandian faults much effort in searching for and understanding postglacial faulting has been concentrated in the previously glaciated regions of northern Europe and North America. These are generally intraplate, continental regions which are not very seismically active at present. As many of the countries in these regions: Canada, Sweden, Finland and Russia, are investigating the

feasibility of long term storage of high-level nuclear waste, which require safety assessments spanning hundreds of thousands to a million years, the possibility of postglacial faulting contributes significantly to the seismic hazard of such repositories. The connection between postglacial faults and nuclear waste repositories have made the identification of these faults a controversial, and highly debated subject.

Over the years, as more workers have been identifying and analyzing faults related to the latest glaciation in Fennoscandia and North America, these faults have become known as *postglacial*, *endglacial* or *lateglacial* faults, with the name indicating both cause and timing. Other terms emphasize either the cause (*glacially induced* or *glacio-isostatic faults*) or occurrence time (*early Holocene faults*). In the broader context of the effect of glaciations on crustal deformation and seismicity, terms such as *deglaciation seismotectonics* and *glacio-seismotectonics* have been used. The general discussion in this article will use the term *glacially induced* fault to emphasize the effect of glaciers on faulting both during their growth and decay, and to avoid the association to the end of the latest glacial period. The term postglacial fault is the one most commonly used and it will be used here to refer to faults that occurred at the end of, or after a glaciation. For specific faults, when the occurrence time has been associated with the last stage of deglaciation, the term endglacial will be used.

This article will review where glacially induced faults have been observed and much of the focus will be on the faults that occurred at the end of the latest glacial period. Identification of the faults will be discussed, their mechanism of faulting and finally a brief look at the current effect of deglaciation on fault stability and seismicity.

Observations of Glacially Induced Faulting

This section briefly reviews the identification and analysis of glacially induced faults in various regions of the world.

Fennoscandia

Northern Fennoscandia's spectacular endglacial faults (EGFs), in a region often referred to as the Lapland fault province (Fig. 1a), have long been known to the local Sami populations as prominent features in the landscape. The name of the 155 km long Pärvie fault scarp translates from Sami along the lines of "Like a breaking wave," an apt description of how the fault disrupts the gentle mountain terrain in northernmost Sweden (Fig. 1b). First described as late- or postglacial in Finland in the 1960s, subsequent investigations in Finland, Sweden and Norway identified approximately a dozen kilometer-scale fault scarps by the end of the 1980s (reviewed in Kuivamäki et al. 1998; Lagerbäck and Sundh 2008; Olesen et al. 2004). Most faults run in a north-northeasterly direction (Fig. 1a) and have reverse motion offsets with downthrow to the northwest, and inferred dips to the southeast. Generally, the faults have reactivated old, Proterozoic or Archean structures, although not necessarily the most prominent of these. The largest known EGF is the 155 km long Pärvie fault, which has a throw of up to 10 m and which runs just east of the Caledonian mountain front in northernmost Sweden. The Lapland fault province extends into Finnmark in northern Norway and into northwestern Finland. To the south, large EGFs had until recently only been detected down to Burträsk, south of Skellefteå in northern Sweden. However, soft-sediment deformation in varved sequences in south and central Sweden has been attributed to strong seismic shaking during end- and postglacial periods, but without identification of a causative fault (Mörner 2004). Recent LiDAR imagery (Fig. 2) have disclosed a number of new, smaller faults in Lapland, more complex fault systems around some of the larger faults, notably on the central Pärvie fault, and a 5 km long scarp in central Sweden of endglacial origin, albeit yet unconfirmed in bedrock (Smith et al. 2014).

The fault scarps are inferred to have been produced by large earthquakes, evidenced by the ubiquitous occurrences of faulting-related phenomena such as low angle landslides and

Further to the southeast the fault can be seen to displace hummocky moraines just before it disappears (Processed LiDAR image courtesy of Henrik Mikko, Geological Survey of Sweden)

soft-sediment disturbances (seismites). Extensive trenching has been carried out on, and in the vicinity of, some of the more accessible faults and shows both liquefaction phenomena and that faulting occurred as single events rather than repeated movements on the faults. The glacial sediments aid in determining the timing of the earthquakes relative to local deglaciation. Using morphological features associated with ice-flow, glacial melting and marine erosion and deposition (many of the events occurred in areas which at that time were covered by the sea), rupture has been observed to occur just before local deglaciation (the Pärvie fault), during deglaciation, just after local deglaciation (the Lansjärv fault) or later in postglacial times (the

Stuoragurra fault). Deglaciation in northern Fennoscandia occurred approximately 10,000 years ago but absolute dating of the ruptures, and also relative dating of the different scarps, has proven difficult. This is due both to the scarcity, and uncertain origins, of organic material in the ruptured sediments and because the course and chronology of the latest Fennoscandian deglaciation is not well known (Lagerbäck and Sundh 2008).

The Lapland fault province occupies a region mostly between the highest mountains in northern Scandinavia and the center of the Weichselian ice sheet, which is inferred to have been located in the Bay of Bothnia where it reached a thickness of approximately 3 km (Fig. 3a). Although the Weichselian glacial period consisted of a number of stadials, the whole region is well within the subsidence bowl of the maximum extent of the Weichselian ice sheet at the last glacial maximum (LGM), as shown clearly even today by the current glacial rebound field. As such, the horizontal flexural stresses in the region have been compressional, and most likely of significant magnitude, during much of the glacial period (see the example of one possible model realization in Fig. 3b).

Earthquake moment magnitude is calculated from the rupture area, the amount of slip and the shear modulus of the rock. First-order estimates of the endglacial earthquake magnitudes can be obtained from empirical relationships between the surface rupture length and magnitude. More accurate estimates need better constraints on the width of the fault plane, on the slip distribution in the earthquake and the shear modulus. Current microearthquake activity on the faults suggests that they are seismogenic down to at least 35 km depth (Arvidsson 1996; Juhlin and Lund 2011; Lindblom et al. 2014). The dip of the fault planes at depth is poorly constrained, but recent reflection seismic and microearthquake investigations indicate that the dip of the Pärvie and Burträsk faults are around 60° to the southeast (Juhlin et al. 2010; Juhlin and Lund 2011; Lindblom et al. 2014). Assuming that the current seismicity reflects the downdip extent of the rupture planes, the width of the fault planes can then be

calculated. The slip distributions, or even the average slip, on the faults cannot be estimated with any certainty. One available option is to use relations of surface rupture offset to slip

distribution estimates for similarly large reverse faulting earthquakes today. It is, however, still unclear if rupture of endglacial faults is similar to that of “regular” tectonic earthquakes, or if the

relatively higher stresses produced at shallow depths by the ice produce relatively more shallow slip, thereby making such comparisons less relevant. With these limitations in mind, the large endglacial earthquakes in Lapland have estimated magnitudes between 7 and 8.

As alluded to above, the endglacial faults of northern Scandinavia are still seismically active (Arvidsson 1996; Lindblom et al. 2014). In fact, most of the earthquakes in northern Sweden occur in the vicinity of an endglacial fault, and all the major endglacial faults in northern Sweden and Norway are seismically active. Recent installations of seismic stations in the vicinity of the Suasselkä and Pasmajärvi faults in Finland indicate that these also host microearthquakes, albeit at a lower rate of activity. The magnitudes of the current earthquakes on the faults reach 3.6 for events that have well determined locations. There are indications that historic events of magnitude approximately 4.5 can be associated with some of the endglacial faults. The cause of the current activity is debated and includes hypotheses such as current tectonic strain release in significantly weakened zones or aftershocks to the endglacial events. In spite of the pervasive microseismicity, it has not been possible to detect any fault movement at the surface since the time of rupture, neither using geological indicators, GPS nor InSAR (Mantovani and Scherneck 2013).

Scotland

The ice sheet over Great Britain was significantly smaller and thinner than the Fennoscandian ice sheet, although it was at times connected to the Fennoscandian ice through an ice bridge across the North Sea. Early investigations of postglacial tectonics in Scotland identified displaced late- and postglacial shorelines in the Firth of Forth and the former ice-dammed lake in Glen Roy. Further work in Scotland indicated that a number of fault offsets were spatially and temporally associated with seismically induced features such as landslides and liquefied sediments (Fenton 1992; Ringrose 1989) and reported

10–100 m of horizontal displacements on 1–14 km long faults. Later investigations in the northwest Highlands have questioned some of the earlier work, especially the evidence for significant strike-slip faulting (Firth and Stewart 2000). Although the study still considered the lateglacial and early Holocene period as significantly seismically active, postglacial faulting was found to be limited to meter-scale vertical movements along pre-existing faults. Interestingly, all examples of postglacial seismicity in Scotland have been attributed to the disappearance of the smaller ice cap developed during the Younger Dryas, and not the deglaciation of the main British ice sheet (Firth and Stewart 2000). Current seismicity in Scotland does not seem to concentrate at inferred postglacial faults, nor does it correlate well with the center of uplift. The seismicity is highly variable, but have been suggested to cluster at the limits of the former ice-sheet, or in areas of local uplift anomalies (Firth and Stewart 2000).

Other European Observations

Smaller-scale structures inferred to be glacially induced have been identified in a number of areas around Europe. Close to the Fennoscandian ice sheet there are reports of faults in Russian Karelia with postglacial movement. Initially inferred to have repeated earthquakes, later analysis favor a “one-off” deformation phase approximately 11 kyr BP but found a seismic origin difficult to confirm (Kuivamäki et al. 1998).

In Germany, shallow meter-scale faults and folds were identified in a sand-pit in Upper Pleistocene alluvial-aeolian deposits 1 km away from the Osning Thrust, a major fault system in central Europe (Brandes et al. 2012). The faults have experienced normal faulting motion some 16–13 kyr ago, when the area was in the forebulge of the Fennoscandian ice sheet. Later, during deglaciation reverse motion occurred, inferred to be due to the N-S directed compressional stress field in northern Germany. Glaciotectonics has been ruled out since the faults are south of the maximum extent of the ice sheet.

In Siekierki near the Polish/German border, soft-sediment deformation structures have recently been interpreted as seismites due to glacially induced earthquakes during the Saalian deglaciation 120 kyr ago (Van Loon and Pisarska-Jamroży 2014). However, no causative fault was identified.

In Northern Iceland, the Kerlingar normal fault runs subparallel to the Northern Volcanic Zone (NVZ), but east of the zone itself. It is an unusually long normal fault with throw down to the east and it is not parallel to the fissure swarms in the NVZ (Hjartardóttir et al. 2010). Hjartardóttir et al. (2010) suggests that the Kerlingar fault formed shortly after the late Pleistocene deglaciation due to isostatic rebound with differential movements between two adjacent crustal domains.

North America

Postglacial faults were first described in 1843, in New York State (Mather 1843), although at that time neither the theory of global glacial periods, nor the concept of postglacial faulting were known. The offset grooves and scratches observed by Mather (1843) were in fact glacial striations. Several other observations of small-scale postglacial faults with offsets of a few millimeters were reported from northeastern USA and eastern Canada during the early twentieth century, and many more during the latter part of the century (Fenton 1994). To date, only two large scale phenomena in Canada have been proposed as large post- or endglacial faults: the Aspy fault on Cape Breton Island and the differential uplift at Peel Sound in Arctic Canada. The Aspy Fault offsets an 125,000 year old intertidal rock platform by 15 m, but has no exposed fault scarp, and the surficial deposits show no evidence of Holocene movement (Adams 1996). At Peel Sound, the marine beaches on opposite sides of the sound are tilted and have differential uplift of over 60 m, which is inferred to have occurred during a short period of time 9,000 years ago. The feature controlling this movement is apparently beneath the sound, but it has not been

possible to identify a causative fault, or to show that the uplift is related to earthquakes at all (Adams 1996).

In the more tectonically active western parts of North America there have only been a few reports indicative of postglacial faulting: a spectacular fault scarp with suspected postglacial movements in the eastern Sierra Nevada, California, postglacial offsets in Archean basement rock in Montana and indications that glacial loading and unloading in Puget Sound may have controlled the timing of movements on the Seattle fault, above the Cascadia subduction zone (see review in Munier and Fenton 2004).

The Wasatch and Teton faults in the Basin-and-Range province in western USA show an increase in slip rate in the late Pleistocene and in the Holocene (see review in Hampel et al. 2010). This has been interpreted as a response to unloading due to the disappearance of Lake Bonneville and the Yellowstone ice cap, respectively, at the end of the latest glacial period (Hampel et al. 2010).

Grollimund and Zoback (2001) suggested that stresses induced by the Laurentide ice sheet affected the Reelfoot Rift in Missouri, USA, and triggered the New Madrid earthquakes of 1811–1812. Later models indicate, however, that such triggering is unlikely (Wu and Johnston 2000).

South America

Investigations from a bog at Puerto del Hambre in the southern Strait of Magellan indicate that the ground surface was downfaulted by at least 30 m sometime between the occupation of the strait by a proglacial lake (12,640–10,315 ^{14}C years BP) and the marine incursion of the site at 8,265 ^{14}C years BP (Bentley and McCulloch 2005). This inferred postglacial faulting seems not to have been associated with one or more large earthquakes, as sediment cores from the area do not show any indication of soft-sediment deformation, slumping, liquefaction or other disturbances to the overall stratigraphy.

Identification of Glacially Induced Faults

As discussed in the Introduction, the identification of postglacial faults has been an intensively debated issue both in Scandinavia and in Canada. Identifying glacially induced faulting and earthquake activity is non-trivial as the surface expressions produced must be distinguished from similar phenomena created by other processes such as glacial movement, ice-water interactions, gravity and temperature. It is also important, not least from a seismic hazard point of view, to distinguish “one-off” postglacial faulting from other neotectonic faulting which may “just” have long recurrence times.

As the physical characteristics of postglacial faulting, tectonic faulting and glaciotectionic deformation overlap, no single criterion can uniquely distinguish them. Instead, multiple lines of evidence need to be assembled for a correct classification. Several identification and classification schemes have been proposed and discussed over the years (see review in Munier and Fenton 2004), the scheme by Muir-Wood (1993) has for example been widely used in Fennoscandia and Canada to differentiate between postglacial faulting and glaciotectionic deformation. It contains the following key criteria, which should all be fulfilled:

1. The surface or material that appears to be offset has to have originally formed as a continuous, unbroken unit. Can the surface be dated? Is it the same age?
2. Can the apparent evidence of an offset be shown to be related directly to a fault?
3. Is the ratio of displacement to overall length of the feature less than 1:1,000? For most faults this ratio, a function of the strength of the rock prior to fault rupture, is between 1:10,000 and 1:100,000.
4. Is the displacement reasonably consistent along the length of the feature?
5. Can the movement be shown to be synchronous along its entire length?

However, a simple list like the above rarely covers all the variations in scales and postglacial

deformation styles in the various glaciated or previously glaciated regions of the world (Munier and Fenton 2004). Detailed investigations at a variety of scales and with multiple techniques are essential in identifying the two over-arching attributes of postglacial faults; their age and their underlying driving mechanism.

The techniques used to investigate postglacial faults are similar to those employed in most regular paleoseismic investigations. In searching for possible candidates in the vast, sparsely inhabited areas of Fennoscandia and Canada, the analysis of stereoscopic aerial photographs has been very successful. As referred to above, LiDAR based digital elevation models nowadays provide unprecedented resolution of features on the Earth's surface (Fig. 2), even through dense vegetation. The LiDAR images not only provide a tool to identify faults and landslides, they are also used to analyze glacial landforms and their spatial relation to the faults. Detailed field mapping is essential to understand regional and local stratigraphy and geomorphic development, in order to aid in determining both the formation process and the age. Geophysical investigations such as magnetics, gravity, ground penetrating radar, sonar profiling (in lakes) and reflection seismic profiling, geodesy and local earthquake seismology reveal various aspects of fault geometry and conditions. Trenching is vital to gain higher confidence in the style of faulting and the age determination, and to investigate fault reactivation patterns. Finally, drilling is used to investigate shallow fault geometry and to determine mechanical, chemical and hydrological properties of the fault.

Mechanics of Glacially Induced Faulting

Although the effects of glaciers and ice sheets on fault stability and seismicity had already received some attention, interest in the topic increased significantly with the observation that there are very few earthquakes below Greenland and Antarctica (Johnston 1987). The analysis indicated that as the ice load increases on the crust, both

Paleoseismology of Glaciated Terrain, Fig. 4 Schematic stress evolution at a fixed location in the upper crust during a glacial period. Pre-existing (e.g., tectonic) stress field (black), glacially induced stresses: direct elastic load (blue), flexural (red). (1) Shortly before

glaciation. (2) During glaciation. (3) Shortly after deglaciation. Note that neither the vertical displacement nor the arrows are to scale (Adapted from a figure courtesy of B. Fälvh, Uppsala University)

vertical and horizontal stresses increase and thereby stabilize faults (Fig. 4). In Mohr-Coulomb terms, the increase in average stress moves the Mohr-circle to the right, away from the failure envelope. Subsequent progress in modelling glacial isostatic adjustment (GIA) made it possible to refine the analysis of fault stability by including flexural stresses and temporal stress variations due to the viscosity of the mantle (e.g., Wu and Hasegawa 1996). Glacially induced stresses under large ice sheets can amount to 30–40 MPa both horizontally and vertically, depending on the size of the ice sheet and the rheology of the Earth. Although seemingly large, they are only 10–15 % of the weight of the overburden at 10 km depth, appropriate for earthquake nucleation. In addition, there are tectonic, topographic, sediment induced and other stresses that can be significant in a specific area (Fig. 4). It is important that all these stresses, the full stress field, is included in the analysis of fault stability as it is the total stress that determines the stress state, which fault orientations that are most easily activated and the stability of these (e.g., Lund et al. 2009).

Not generally included in the GIA based models is the accumulation of tectonic stress

during glaciation. Although much smaller than the glacially induced stress variations, at least in continental interiors, there can be enough stress accumulated during the cause of a glacial period to significantly affect the stability of faults once the stabilizing effect of the ice is disappearing (Johnston 1989). Over even longer time periods, such as the duration of the Greenland or Antarctic ice sheets, tectonic loading may even be able to bring faults back towards frictional equilibrium, and hence destabilize them again in spite of the overriding ice sheet (Stewart et al. 2000).

Modelling Glacially Induced Stresses

GIA models have primarily been concerned with the rates of vertical uplift through time in order to fit observations of Holocene sea-level rise, historical tide-gauge data and recent satellite based data, e.g., GPS, InSAR and GRACE gravity. Such studies have provided a wealth of information on climate, ice sheet configuration and evolution, and the rheology of the Earth. The emergence of suitable finite element models provided a convenient tool to investigate the stress field induced in the crust by a glaciation, and thus

the mechanisms of glacially induced faulting (Wu and Hasegawa 1996). The stress field that develops in the Earth due to the ice load depends both on the ice load itself and the rheological and elastic structure of the Earth. Even during glacial periods the large ice sheets evolve constantly, it is nowadays well established that during the latest glaciation, in the last 100,000 years, the ice sheets grew and declined several times and therefore had very varying extent and thickness. Crustal stresses evolve, to first order, with the ice load implying that a good ice model is vital in GIA modelling (e.g., Schmidt et al. 2014).

As outlined above, the growth of an ice sheet and the subsequent down-warping of the Earth's elastic lithosphere induces vertical stress in the Earth proportional to the ice load. It also induces horizontal stresses which are a combination of the Poisson effect of the load and the flexural stresses that develop as the lithosphere bends (Fig. 4). The horizontal stresses will be compressive in the upper part of the lithosphere under the load, and tensional outside the load in the so called fore-bulge. Under the load, the vertical stresses will initially be larger than the horizontal as flexure develops slowly due to the slow flow of the mantle. This produces an induced normal faulting stress regime. As the ice sheet stops growing, horizontal stress magnitudes will generally catch-up, and surpass, the vertical, inducing a strike-slip state of stress. During deglaciation the vertical stress decreases much more rapidly than the horizontal stresses, again due to the slower response of the mantle, such that the stress field will evolve to a reverse state. During and after deglaciation the uplift of the formerly glaciated region will decrease the compression in the upper crust, as the collapse of the fore-bulge will decrease the induced tension in the crust. The inward migration of the fore-bulge may produce induced tensional stresses in areas that were previously subjected to compressional glacial stresses.

Second only to the ice load itself, the rheology and elasticity of the Earth model has a major influence on the glacially induced stresses. For a certain ice load, the elastic structure determines

the magnitude of the stresses, which is especially important in the upper crust, where the glacial stresses are the largest. A high resolution layered, or three-dimensional, structure is vital in order to not significantly over-estimate the stress magnitudes in the uppermost crust. A laterally varying thickness of the elastic part of the lithosphere, and lateral variations of the parameters within the lithosphere, also affects the magnitude of the stress field and its spatial variation (Lund et al. 2009). The viscosity of the mantle, including lateral variations and non-linear rheology, strongly affects the temporal evolution of stress magnitudes outside the LGM ice margin, but has little effect inside the margin (e.g., Wu et al. 1999). The interaction of the ice load with Earth structure produces some interesting effects. The horizontal stress magnitudes induced by flexure of the elastic lithosphere depend on the spatial extent of the ice sheet relative to the thickness of the elastic lithosphere (Johnston et al. 1998). Accordingly, for commonly inferred lithospheric thicknesses, a smaller ice sheet, the size of the former British ice sheet, would produce maximum amplification of the horizontal stresses. The Fennoscandian ice sheet would similarly produce higher flexural stresses than the North American ice sheet, consistent with the observation of large endglacial fault in northern Fennoscandia.

Fault Stability

The GIA models discussed above have included neither a pre-existing stress field nor pre-defined faults. Instead, fault stability has been evaluated in post-processing, where the modelled glacially induced stresses have been added to a pre-existing stress field and areas and times susceptible to faulting have been studied. Faulting potential is commonly investigated using Mohr-Coulomb theory, through changes either in the Coulomb Failure Stress ($CFS = \tau - \mu(\sigma_n - P_p)$), where τ is the shear stress on a fault, σ_n the normal stress, μ the coefficient of friction and P_p the pore pressure

Paleoseismology of Glaciated Terrain, Fig. 5 Variation in fault stability at a location centrally under the ice sheet, from prior to the glaciation (blue lines), to LGM (a, red lines) and to the end of glaciation

(EoG, green lines) for pre-existing reverse (b), strike-slip (c) and normal (d) stress fields. (a) applies to all pre-existing stress fields as it is assumed here that the glacially induced stress field is isotropic ($\sigma_1^G = \sigma_2^G = \sigma_3^G$)

(e.g., Lund 2005), or the similar fault stability margin (Wu and Hasegawa 1996).

The models generally show that for a stable continental interior, with a preexisting stress field in a state of reverse faulting, the region within the LGM ice margin is stabilized by the growth of an ice sheet. Towards the end of deglaciation, as the vertical stress diminishes much faster than the horizontal stresses, optimally oriented faults in the region centrally under the ice sheet tend to become unstable (Fig. 5 and Lund et al. 2009; Wu et al. 1999). This model agrees well with the occurrence of the endglacial earthquakes in northern Fennoscandia, both in timing and strike direction (Lund et al. 2009). For strike-slip or normal faulting stress fields it is not the interior (Fig. 5c, d) but the areas outside the LGM ice margin that are affected by fault instability, not only at the time of deglaciation but also during times of glacier advance and stand still. The stability of the fore-bulge region depends very much on the details of ice and Earth models, and is as such less well constrained.

Fault stability and earthquake occurrence depend on more factors than just the state of stress. Pore pressure is a vital parameter in the analysis of faulting, and pore pressures in the crust during deglaciation are notoriously difficult to estimate due to the lack of data. The Fennoscandian ice sheet was cold based for much of the latest glacial period (Lagerbäck and Sundh 2008) and it is likely that permafrost could have existed in the crust below the ice for long periods of time. Without a hydraulic head, it is uncertain how pore pressure in the crust would be affected by the ice and permafrost. If there was hydraulic contact between water in the ice sheet and crustal pore fluids, high pore pressures would have been able to penetrate deep into the crust during the long duration of the ice sheet (e.g., Lönnqvist and Hökmark 2013). The combination of high pore pressures and permafrost could potentially have maintained higher than hydrostatic pressures in the crust during deglaciation, adding to the instability of faults.

In a further advancement of finite element based GIA models it has become possible to

explicitly include faults and pre-existing stresses. Early models imposed velocity boundary conditions to have faults slip at a constant rate prior to glaciation, thereby including tectonic stressing rates, but did not include the deep mantle (see Hampel et al. 2010). The models agree with previous results but more explicitly show the inhibition of slip during glaciation and rapid slip increase at deglaciation. Later models include a proper mantle description and come to similar conclusions (Steffen et al. 2014), although still in a state of early development.

Effects of Current Deglaciation

The current global warming trend increases melting of ice sheets and glaciers worldwide. Does this deglaciation influence seismicity rates in the affected regions? Areas that are glaciated and tectonically active, such as Iceland and Alaska, are good candidates for investigations of the process but few studies have been attempted. Although glacier thinning rates may have increased, the time scales involved, compared to the time of good seismic network coverage, make it difficult to establish solid background rates to compare to. A glacier surge in Alaska affected local seismicity by increasing it in the surge reservoir region and decreasing it in the receiving region, in agreement with predictions for a compressive tectonic stress state (Sauber and Molnia 2004). Also in Alaska, stress changes due to retreating ice in the Icy Bay area in the 80 years between the 1899 Yakataga (M_W 8.1) and Yakutat (M_W 8.1) earthquakes and the 1979 St. Elias (M_S 7.2) earthquake are inferred to have decreased the stability of the St. Elias fault system by 2–3 MPa (Sauber and Molnia 2004). In Iceland, the current thinning of the Vatnajökull glacier has been suggested to contribute to high seismicity and unusual focal mechanisms (Pagli and Sigmundsson 2008). Assessing how the glacially induced stress change affects earthquake activity in Iceland is, however, non-trivial as time

varying stresses from volcanic activity and rifting are active in the glaciated region.

In the areas of the two remaining continental ice sheets, Greenland and Antarctica, significantly increased seismic detection capabilities have not seriously challenged the more than 25 year old hypothesis of ice sheets as inhibitors of seismic activity. There is significant earthquake activity along the margins of the Greenland ice sheet but very little in the interior (i.e., Olivieri and Spada 2014). There has been suggestions that glacial isostatic adjustment from the Pleistocene deglaciation still affects the occurrence and mechanisms of earthquakes off the coast of Greenland (Chung 2002), and that the seismicity is affected by elastic rebound stresses from the current thinning. The data is currently too sparse to distinguish between these processes and to validate any of them with numerical models (Olivieri and Spada 2014). What is clear, however, is that the current rapid thinning of outlet glaciers in Greenland cause significant ice-related events, so called glacial earthquakes or ice-quakes (e.g. Ekström et al. 2006). Similarly, in Antarctica there is significant ice-quake activity in ice streams and outlet glaciers, but very few earthquakes detected in the continent itself. Recent investigations have, however, found swarms of seismic activity inferred to be caused by magmatic activity in West Antarctica (Lough et al. 2013).

Summary

Loads on the crust caused by glaciers and ice sheets can have a significant effect on earthquake occurrence, as indicated by the large fault scarps in northern Fennoscandia caused by earthquakes at the end of the latest glaciation, and the current seismic quiescence under the Greenland and Antarctic ice sheets. Therefore, the assessment of long term seismic hazard in regions affected by glaciation need to take this effect into account.

A large number of observations of faulting in North America and Northern Europe indicate that

these intraplate, continental regions experienced a substantial increase in seismicity as the ice sheets of the latest glaciation disappeared. In the Lapland fault province in northern Fennoscandia a dozen fault scarps, ranging in length from a few tens of kilometers to 155 km, have been associated with one-step rupture at the end of the deglaciation phase. The association to earthquake rupture comes from detailed investigations of soft-sediment disturbances such as landslides, seismites and stratigraphic offsets in trenches. These investigations also determine the age of faulting relative to the glacial sediments. The magnitudes of the largest endglacial earthquakes have been estimated as M_w 7–8 using fault scarp lengths, fault planes delineated by current microseismicity and empirical scaling relations. Postglacial fault observations in Scotland and Canada generally show shorter lengths and smaller offsets, although there are a few observations of larger scale postglacial phenomena where the cause has not been properly identified. Outside the margin of the former maximum extent of the ice sheets, such as in Germany and USA, glacially induced faulting has been identified or suggested, not necessarily contemporaneous with the latest deglaciation.

Identification of glacially induced faulting is non-trivial as the faults, or faulting related disturbances, first have to be distinguished from structures related to glaciotectionic processes. Then, identified faults have to be shown to have a glacially related origin and not be due to other neotectonic processes. Several classification schemes exist, which all suggest that a wide variety of data should be collected prior to decision making. Areal, satellite, ground mapping, geophysics, trenching and drilling data all provide complementary evidence of fault age and driving mechanisms.

Rapid model development and increase in computing power has enabled more complex models of glacial isostatic adjustment (GIA) and fault stability. A glacier load bends the elastic upper lithosphere down into the softer asthenosphere, inducing both directly load related

stresses and flexural stress in the crust. The load tends to stabilize faults inside the load margin, but may destabilize faults outside the margin, depending on the pre-existing stress field. During deglaciation, the vertical stress decreases more rapidly than the horizontal stresses due to the delayed response of the asthenosphere. If the pre-existing stress field inside the former ice margin is suitably oriented, faults may become destabilized. Outside the margin the fore-bulge will collapse and move inward, destabilizing faults if the pre-existing stress conditions combine favorably with the glacial stresses. The latest model generation includes actual faults and can estimate fault offsets in simulated earthquakes. In addition to direct load and flexural stresses, tectonic horizontal stresses may accumulate under the stabilizing weight of the ice sheets. Stress accumulation is generally slow in cratonic interiors and uncertainties in the accumulation rates makes the relative importance of the process debatable. The GIA models can currently to some degree predict location, orientation and onset times of glacially induced fault instability. However, there is still need for considerable progress in understanding the details of endglacial fault mechanisms in terms of location, geometry and size.

Improved models of glacially induced seismicity will allow better prediction of what may happen as glaciers and ice sheets decrease in the current global warming trend. The evidence for current crustal scale deglaciation related seismicity is scarce but it may increase in the next century, emphasizing the need for better seismic hazard estimates in the vicinity of thinning ice sheets.

Introduction: The Importance of Trenching in Paleoseismology

Trenching on a fault trace is a direct way to understand the historical (mainly Holocene) evolution of a fault segment. What are signatures of past earthquakes at the Earth's surface? How do we recognize and identify past (paleo-) earthquakes? One of the most famous and fundamental principles of modern geology, “the present is the key to the past,” provides the answer, from which historical seismic events are accepted to have the same effect as modern ones do. However, the incompleteness of the historical record makes it hard to determine and identify

paleo-earthquake-related structures. The discrimination of paleoseismic evidences from geological and geomorphological processes and the attribution of them to certain historical events make an important contribution to the seismic risk assessment of any region.

Paleoseismology is the art of the identification of past earthquakes in terms of location, timing, and size by using geological and geomorphological evidence (McCalpin 2009). This branch of Earth science is mainly based on the interpretation of features recorded and preserved by depositional and erosional processes. Paleoseismology addresses a specific timescale that connects neotectonics and instrumental seismology, mostly from the Late Pleistocene to the present day. A detailed paleoseismic study can reveal a seismic history even going back several thousand years. Characterizing past earthquake parameters (e.g., fault location, earthquake magnitude, and recurrence interval) helps construct a strong database, which can be used in the modeling of potential seismic hazards.

However, there are no fixed or standard techniques for the study of past earthquake records. Accordingly, different methods and approaches must be specifically applied to each individual case. The most widely used and effective method is the trenching of recent deposits across active faults. The aim of trenching is to expose the stratigraphic and structural relationships of buried modern deposits and to discriminate the signature of paleo-events. A paleoseismologist determines the timing of identified earthquakes by using various Quaternary-dating methods allowing correlation with historical documents. The main target of a paleoseismic study is to understand the history of studied fault segment(s) and to develop a knowledge base for establishing the location and magnitude of future earthquakes for the same region. Paleoseismic results play a vital role for seismic risk assessments. This chapter aims to summarize the main steps undertaken during a paleoseismic trenching study. The most commonly used dating methods in paleoseismology are also briefly outlined.

Flowchart in Trenching Studies

The identification of a paleo-event, its dating, and its correlation with a historical earthquake is the main objective of a paleoseismic study. However, to reach that final goal, there are several steps that need to be undertaken, such as site location, logistic settings, selection of the trench type, taking of safety precautions, preparation of trench walls for logging, sampling for dating, and post-field studies, which will all be briefly mentioned in the following sections.

Site Selection: Geoinformatics, In Situ Observations, Shallow Geophysical Methods, and the Micro-Topographic Surveys

The determination of a suitable site plays a fundamental role in paleoseismology. Not only finding the fault trace but also exposing the suitable sedimentation is crucial for the recovery of a paleo-event in a trench study. Although the techniques may differ from region to region, the general sequence of investigations start with geoinformatics, continue with in situ observations, and usually end with the application of shallow geophysical and micro-topographic surveys.

Geoinformatics: Remote Sensing and Geographic Information Systems (GIS)

Aerial photographs are one of the main sources used in the identification of faults and other tectonic landforms. Analyses of aerial photograph stereopairs allow easily visualization of pseudo-3D reflections of the study region in a 2D environment. Skilled researchers can easily interpret fault scarps and tectonic landforms by using aerial photographs of actively deformed regions. Detailed topographic datasets also assist in the interpretation of physiographic features. Technological progress has greatly advanced remote sensing abilities. For example, one of the latest commercial satellites, Geoeye-2, is planned to start collecting satellite images of the Earth with a ground resolution up to 0.34 m by the second half of 2013 (GeoEye Elevating Insight 2013).

Moreover, advances in LiDAR (Light Detection and Ranging) and high computational technologies make the analysis of high-resolution digital elevation models (DEM) possible. These topographic data with submeter pixel resolution not only provide the easy identification of fault scarps but also yield auto-quantification of displacements (Zielke and Arrowsmith 2012) or precise mapping of seismogenic faults even in highly forested mountainous terrains (e.g., Cunningham et al. 2006). It is possible to merge all these products in a GIS database and to make sophisticated spatial analyses of tectonic landforms in site selection for trenching. These modern tools can focus attention on small study areas; thereby they significantly save time and reduce budgets in paleoseismological projects.

In Situ Observations: Geological and Geomorphological Mapping

To understand geometrical relations among recent (late Quaternary) geological units, and sometimes between older rocks and recent deposits, geological mapping of units and landforms of a trench site should be undertaken. Detailed mapping can also identify piercing points (i.e., offset features) along or across faults. Remote sensing analysis on the region of interest is controlled with field observations during the mapping of geological and geomorphological features. Mapping usually includes fault scarps and detailed subdivisions of Quaternary deposits across the fault. The paleoseismic history is interpreted from the constructed relationship of the mapped Quaternary deposits and the faulting pattern. The displacement measurements are often indicated on these maps. Beside the mapped features, the depositional conditions and sedimentary sources of the site are studied to gather the maximum information for understanding the local stratigraphy before trenching.

Modern depositional and erosional processes at a paleoseismic site supply data so that the trench stratigraphy can be interpreted. Paleoseismologists mostly prefer fine-grained sediments, where slow sedimentation rates allow an older

history to be recorded at relatively shallower depths. However, boulder- and cobble-rich sediments can be deposited abruptly and can instantaneously cover paleo-events. Furthermore, it is also difficult to recognize deformational structures within these coarse-grained sediments. As a result, mixed sedimentary environments such as fluvial and alluvial rivers (mostly floodplains and point bars), seasonal swamps, marshes, sag ponds, deltas, alluvial fans (especially the distal part), piedmonts, and deserts are the ideal for paleoseismic trenching.

Colluvium in front of the fault scarp is one of the most important depositional features recording the material shed from the uplifted fault block. The clast type, size, and shape that form colluvial deposits depend on the lithology of uplifted block but may also change laterally from proximal to distal parts.

Shallow Geophysical Methods

Geophysical exploration methods have a critical role for detecting the exact location of main faults and any subsidiary branches. The application of geophysical techniques can be useful in definition of the stratigraphy and the deeper structure of the fault zone, aspects that cannot be determined by trenching or drilling. Geophysical methods are often applied in regions where tectonic landforms are buried and cannot be identified by surficial observations. The most commonly used geophysical methods are seismic reflection/refraction, ground-penetrating radar (GPR), and electric, magnetic (aero and electro), and gravity techniques in paleoseismological studies. For example, along the 1999 İzmit earthquake rupture (North Anatolian Fault, Turkey), GPR profiles clearly show not only the fault zone but also displaced fluvial channels of different ages (Ferry et al. 2004). In addition to 2D representations, for faults with a more complicated tectonic setting, 3D GPR images are needed to constrain fault structure, such as demonstrated on the hidden faults in the transpressional setting of the Alpine Fault (South Island, New Zealand) (Carpentier et al. 2012).

Micro-Topographic Surveys: Construction of Very High-Detailed Morphology

Before the excavation of a natural surface on a trenching site, detailed surveying of the morphology of the field can reveal landscape anomalies, which cannot be easily recognized with the naked eye. Interpretation of high-resolution topographic data can be used to analyze the effect of tectonic activity in the formation of such morphological features. A quantitative assessment of morphological structures provides detailed information especially about the likely characteristics of the faulting. Moreover, well-defined and well-analyzed detailed morphology also decreases the excavation length (and time) at a probable trench site. Toward this goal, micro-topography and the related physiographic features can be measured by using instruments such as the electronic theodolite (total station), d-GPS (or RTK GPS), and the terrestrial LiDAR (TLS) in the field. With the introduction of the high-resolution topographic data collection of the TLS, it is even now possible to constrain the 3D-slip vectors recorded by displaced landforms (Gold et al. 2012). Not only detailed topographic maps but also topographic profiles across fault zones provide invaluable information about the history of deformation.

Final Decision: Site Selection

The best location for a trench is highly site dependent. The site selection is undertaken through the synthesis of all datasets and studies, which are briefly listed above. All combined data are interpreted to identify two (or alternatively three) targets in a trench study in order to expose (a) the full rupture geometry and the style of faulting; (b) the stratigraphy, which reflects the most complete depositional history; and (c) any buried displaced feature, if present. For the first goal, it is important to stay on the main fault strand, which records the most complete seismic history of the deformation zone. However, it is also common to target trench studies on secondary faults. Pantosti et al. (2008) preferred to excavate one of their trenches on an antithetic fault scarp instead of the main displacement zone, because of logistic reasons. Secondly, a paleoseismologist always tries to find the most

suitable place with a continuous sedimentation for the most complete stratigraphic record. Even depositional environments with very slow sedimentation rates can be chosen for slow-moving faults, like the Alhama de Murcia Fault (Eastern Betic shear zone, Spain) to expose a longer paleoseismic record (Ortuño et al. 2012). These first two objectives mostly yield the recovery of location and timing of a faulting event by fault-perpendicular trenches. However, on strike-slip faults, the magnitude of displacement can only be obtained with fault-parallel trenches, where buried and laterally displaced features are exposed.

Logistics: Administrative and Environmental Issues

Administrative Issues: Local and Governmental Permissions

Following the site selection, one of the mandatory issues is getting excavation permissions both from local (land owners) and administrative authorities. If the site is located in an archeological site or is close to a military base, then additional permissions may be required.

On cultivated lands, firstly, it is important to get the permission of the landowner but the local authorities must also be informed. The contact also provides logistic information for researchers about the existence of any possible human-made structures, such as waterworks, electricity cables, and oil/gas pipelines, which can easily be destroyed during a trench excavation. Moreover, these authorities, like local municipalities, may help in finding the work machines, which are used in trenching.

Environmental Issues: Water Table, Geography, and Transportation

The high water table in a site can cause the collapse of trench walls or it can make almost impossible for researchers to move inside the trench. The dewatering for a more pleasant working space is done in two general ways: (a) periodically pumping the water out of the trench and releasing it some distance away, and (b) draining the water by digging a shallow pit downslope from the toe of the trench. Also, the

drier season is selected to have a lower water table as much possible in most cases.

It ought to be possible to find a proper work machine for excavation (e.g., backhoe, trackhoe, or bulldozer) in most study areas. But the trench location may be located too far from a settlement, or there may be no excavation machine around. In such cases, trenches can be dug by hand. Prentice et al. (2002) dug several hand-made trenches even up to several meters in length and depth in Mongolia, where there are no settlements nearby.

The excavation of a site also means the destruction of the local stratigraphy and structures. Therefore, any trenching should be done in the most preservative way to avoid damage both for the ongoing and any future studies at the same site. Moreover, excavation material should be backfilled carefully, especially on cultivated lands. For example, preservation of the natural soil can be critical and can be done by separating it from other excavated materials and putting it back at the end of the trench study.

Excavation: Choosing the Trench Orientation, Size, and Pattern

The choices for trench excavation depend on several factors such as the kind of material being trenched, the width of the deformation zone, the fault type, the relief of the site, the target depth, the stability of the trench walls, and the style of working.

Trench Orientation: Fault-Perpendicular and Fault-Parallel Trenches

The sense of fault displacement is the major criteria in positioning trenches before starting the excavation. Fault-perpendicular trenches are often used to locate fault zones and identify the recurrence patterns. Dip-slip paleo-events can be characterized in terms of recurrence and displacement by a single fault-perpendicular trench, especially where the deformation is localized in a narrow zone. However, multiple trenches, both fault-perpendicular and fault-parallel, are needed to measure the horizontal slip along strike-slip faults. The concept of 3D trenching was developed for this type of faulting, where both

recurrence and displacement history could be inferred. To reveal the slip history, several approaches could be used, such as (a) multiple trenches closely spaced; (b) successive exposures, which are dug orthogonally to the fault zone; or (c) two fault-parallel trenches on each side of the fault, exposing the offset features (piercing lines). In all of these approaches, at least one fault-perpendicular trench is excavated to locate the fault zone. For example, Marco et al. (2005) used buried stream channels as piercing lines to restore the slip history of individual and cumulative events at the Jordan Gorge Segment of the Dead Sea Fault.

Trench Size

The main goal in trench studies is to expose maximum information with the most efficient excavation. Thus, determination of excavation dimensions plays a crucial role in the planning of the study time and budget. Depending on the width of the fault zone, the trench length may vary from a few meters to several hundred meters. Excavations are often started from foot-wall side and extended toward the hanging wall across dip-slip faults. The trench length is relatively shorter across strike-slip faults. The width is preferred to be large enough for the maintenance of a safe and comfortable working space, especially for taking photos of the trench walls. Depth mostly depends on the stability of walls and water table. Deeper trenches increase the probability of exposing a longer seismic history. Safety precautions are also very important in planning of the trench dimensions. (Please see the relevant section in this article). On the other hand, the geometry of trench walls, either oriented vertically or inclined, should have a planar shape as much as possible for a perfect projection surface to log.

Trench Patterns

Trench arrangement usually differs according to the structural and depositional properties of sites. The most appropriate arrangement is mostly selected according to the water table, stability of trench walls, type of deposits, logistic conditions, and the budget. Figure 1 shows cross sections of

Paleoseismic Trenching, Fig. 1 Cross sections showing different types of trench patterns. Type 1, single slot; Type 2, one-side stepped; Type 3, two-side stepped; Type 4, multisteped; Type 5, one-side sloped; Type 6, two-side sloped (or open pit) (Modified and redrawn after McCalpin 1989)

Paleoseismic Trenching, Fig. 2 Sample photos from different trench types: (a) single slot (Photo by Dr. Aynur Dikbaş) and (b) two-side stepped (Photo by Dr. Taylan Sançar)

different trench types (Type 1 to Type 6). The most often used pattern is single-slot (California-style, Type 1) trench, which is easily shored with a minimum material excavation and is least time consuming (Fig. 2a). This style of trenching is also the cheapest one, but also may acquire hydraulic or wooden shores against collapse of trench walls, especially in loose sediments. On the other hand, it is obvious that deeper sections increase the possibility for the recovery of the longer seismic history. Thus, paleoseismologists tend to excavate deeper trenches in suitable

sites (Fig. 2b). Deeper trenches, Type 2 to Type 6, expose more faulting events, but they are expensive and time consuming. Multisteped or sloped patterns are mainly precautions against trench collapse.

Safety Precautions

Trench walls tend to collapse easily under various geological and morphological conditions. Fault zones easily reduce the cohesion of the material by crushing and creating open voids. High water table can evoke the collapse of unconsolidated

young sediments. Cohesion differences between stratigraphic units in a section may also cause caving inside the cohesionless unit. Precautions, which are listed under two subtitles below, include only general and most common suggestions. Local regulations must always be consulted and followed. BS 5930 “the code of practice for site investigations” in the UK, for example, gives detailed guidance on legal, environmental, and technical matters relating to site investigation. It should be well understood that trenching is dangerous and loss of life can occur if undertaken unsafely. All available and mandatory risk assessments should be undertaken prior to work commencing and then reviewed once the trench is open to take into account any unexpected ground conditions.

Safety Precautions Inside the Trench

Trenching in loose materials or high water table may cause collapsing or caving of trench walls. Stepped- or sloped-type trenches are relatively safer with respect to single-slot type based on local conditions. For example, according to safety regulations in the USA, the vertical walls exceeding 1.5 m high in Type A or 1.2 m in Type B and Type C soils must contain another 1.5 m-wide horizontal bench on each side (OSHA 1989). In addition to benching, the stability of walls can be supported by hydraulic or wooden shores (Fig. 2a). If trench walls contain blocky materials, fallen boulders or cobbles can easily harm or even kill researches who work inside. Hard hats should always be worn in any trench over 1 m deep, which can be deadly under the right circumstances.

Safety Precautions Outside the Trench

Trenches with considerable depths are dangerous spots not only for domestic animals but also for the people who live nearby. An excavation area can attract especially kids and curious adults, and closing to the trench edges can be dangerous both for them and researchers inside. Paleoseismologists usually use safety tapes or simple fences to avoid such accidents. One member of the study team should also stay outside not only to inform cautious visitors but also to monitor any

progressive cracks on the ground following the excavation of the site.

Preparing Trench for the Study

Following the excavation and implementation of safety precautions, the walls must be perfectly cleaned enough to expose all stratigraphic and structural relationships. The shovel of work machines usually leaves many scars, clay packs, or pseudo-corrugations. Tools such as scrapers, masonry towels, hammers, brushes, and water sprays are used for the cleaning of different material types on the trench walls.

After a careful cleaning process, a reference grid is constructed for logging. A typical grid is composed of perfect vertical and horizontal lines, which are generally spaced 1 m (or 0.5 m) apart. Horizontality and verticality can be constructed and checked using a spirit level. Laser levelers, which increase the precision and save lots of time, are getting more common each day in trench studies. At the end of gridding, every horizontal and vertical reference point is labeled successively every 1 or 0.5 m (Fig. 3).

Logging: Recording the Stratigraphic and Structural Relationships

Trench logs are the key records, which contain almost all information regarding the stratigraphy and structures in a trench study. These logs not only document primary and/or secondary earthquake evidence, but they also show the precise coordinates of sampling points. In many trench studies, usually a single wall is logged. However, logging of both walls provides confirmation of structural features and also helps the 3D reconstruction of the distribution of stratigraphic units. There are two common logging methods: manual and photomosaic.

Squared paper is used in the traditional manual method, for which each critical stratigraphic horizon and structure is logged with plotting the measurements of critical points with respect to the reference grid (Fig. 4). An ordinary tape measure or a measuring rod with a spirit level is used in taking these coordinates. In manual logging, there must be at least two people working simultaneously for an efficient study.

Paleoseismic Trenching, Fig. 3 An ideal reference grid (Photo by Dr. Volkan Karabacak)

Paleoseismic Trenching, Fig. 4 Traditional manual log of a trench wall (Taken from Dr. Volkan Karabacak)

Paleoseismic Trenching, Fig. 5 Photomosaic of a trench wall (Photo by Dr. Volkan Karabacak)

While one person measures the horizontal and vertical distances from trench features to the nearest grid line, a second person plots the positions of these measurements on the squared paper with a scale.

Especially after the development of the digital photography techniques, logging on the photo-mosaic of walls has almost become a standard in trench studies. The trench walls are photographed and combined into a mosaic covering the whole wall (Fig. 5). Fast orthorectification of photos provide precise representation of trench exposures.

In addition to these two common techniques, there are different methodological attempts in logging of a trench wall. These relatively new methods aim to provide more quantitative information about structures and the distribution of the depositional units by using such as spectral imaging (Ragona et al. 2006) or the magnetic susceptibility measurements of the trench walls (Fraser et al. 2009).

Irrelevant to which method is chosen during the logging, the final record is digitized by using vector-based drawing software in post-field studies. All stratigraphic units are labeled and shown with proper symbols and colors. In addition to the clear imaging of faults and event horizons, the reference grid is provided to give a true spatial sense (Fig. 6).

Types of Sediment-Structure Relations in the Identification of Paleoearthquakes

Destructive earthquakes, mainly with magnitude >6, often produce surface deformation, which depends on parameters such as the physical structure of the crust, the type of faulting, and the focal depth. In a properly selected trench site, it is highly probable to see surface faulting within the young deposits. A key objective of paleoseismologists is to identify and define event horizon(s) and recover

Paleoseismic Trenching, Fig. 6 A final log of a trench study (Taken from Dr. Volkan Karabacak)

the seismic history of the studied fault segment with dating of the relevant stratigraphic units.

Each trench has its own story. The historical evolution of the studied fault segment is hidden on the trench wall exposures. Even though there are some definite event structures for different fault types, all fault-related structures can be classified under two major titles: (a) on-fault (primary) and (b) off-fault (secondary or indirect) structures (Fig. 7). On-fault structures are mostly preferred in trench studies, due to the ambiguous nature of off-fault structures.

On-Fault Structures

The most commonly seen evidence for a past earthquake on the trench wall is upward termination of a fault against overlying strata (Fig. 7a). The thickness change of a layer on both sides of the fault reflects an erosional and depositional stage after an earthquake (Fig. 7b). A colluvial wedge is another clear evidence for a paleo-

surface rupture, where a vertical separation or offset occurs between faulted blocks (this is also possible in lateral fault movements in rugged areas) (Fig. 7c). A monoclinical-like structure develops above the faulted zone in environments with high sedimentation rates (Fig. 7d). Open fissures can often be seen both on extensional and strike-slip faults. They can be filled by younger infills, which mark an event on the trench wall (Fig. 7e). Disoriented pebble- or cobble-sized clasts, seen in coarse-grained layers or in shear zones within fine-grained sediments, usually indicate a surface deformation of an earthquake (Fig. 7f, g).

Off-Fault Structures

Where it is not possible to open a trench on the main fault zone, for a variety of reason, paleoseismologists will then look to examine secondary (or off-fault) structures, to reveal the paleoseismic history. Angular unconformities

Paleoseismic Trenching,

Fig. 7 Earthquake indicators used in the identification of paleo-events. On-fault structures: (a) upward termination of a fault, which is overlain by undeformed stratum; (b) difference in thickness of strata at each side of the fault and downward growth of the displacement along the fault trace; (c) scarp-derived colluvium; (d) formation of monoclinical folding, where fast sedimentation covers the fault scarp; (e) open surface cracks, infilled with material of the overlying unit; (f) disordered pebbles covered by undeformed layer; and (g) sheared layer covered with unshered one. Off-fault structures: (h) angular unconformity within modern sediments; (i) sand boil, sand dike, and liquefied sand; (j) minor cracks and fissures with no offset; and (k) soft-sediment deformation in general that blankets with undeformed one (Modified and redrawn after Allen (1986); reprinted with permission from Active Tectonics (1986) by the National Academy of Sciences, Courtesy of the National Academy Press, Washington, DC)

within the modern sediments are important markers, indicating a nearby fault-related deformation (Fig. 7h). Sandblow (or boil), mud diapirism, liquefied sand, minor fractures, and

cracks are all soft-sediment deformational structures that are related to ground shaking and can be interpreted as indicators of paleo-earthquakes (Fig. 7i-k).

Dating Paleo-earthquakes

In addition to identification of paleo-earthquakes on trench walls, it is crucial to date important seismic horizons to model paleo-earthquakes and future risk. During or after the logging of stratigraphic horizons and structural features on the trench wall, horizons are sampled for dating to construct the temporal relationships. Especially event horizons, which cover earthquake-related structures, are the key levels in the recovery of the seismic history in a trench study. Late Quaternary deposits can be dated by a wide range of correlated, relative, numerical, and calibrated age methods. Among all, radiocarbon dating is the most common applied method in paleoseismological studies. The main materials are in situ organic compounds, such as bones, teeth, shells, charcoals, peats, chunks, and organic soils for radiocarbon dating. Advances in luminescence dating also introduced the application of this method in trench studies. Other dating methods of young sediments such as varve chronology, electron spin resonance, amino acid racemization, etc. can be used in suitable environments. Prior to sampling for dating, the most proper method should be determined, and the careful sampling techniques should be applied to avoid any contamination.

Advantages and Disadvantages of Trenching Studies

Paleoseismic trenching plays an important role in the reconstruction of a seismic history and makes an invaluable contribution to seismic risk assessments of a region (Gürpınar 2005). However, paleoseismology has advantages and limits like any other applied techniques. It is important to know all these aspects of paleoseismic studies to construct a sound project and solve a scientific problem.

The Advantages of Paleoseismic Trenching

- Paleoseismic trenching can provide the exact location of the fault (or deformational structures), which is very important information in urban or industrial planning.

- The reconstruction of the seismic history from well-chosen trench sites provides reliable information for seismic risk assessments.
- In addition to the location and timing of a paleo-event, well-located fault-perpendicular trenches for dip-slip faults or fault-parallel trenches for strike-slip faults provide the slip history (magnitude of displacement).

The Disadvantages of Paleoseismic Trenching

- Sometimes the destructive earthquakes do not produce any surface rupture along the source fault. These kinds of paleo-earthquakes do not leave their surface expressions on the Earth's surface, which make it impossible to identify anything in a trench study. Thus, paleoseismic trenching may only give information for large earthquakes that produce surface deformations.
- The distributed deformation, especially in thick water-saturated sediments, can be reflected as departed surface faulting after different events. Studies, especially with only a single trench under these circumstances, are resulted with missing recovery of total history.
- The thickness of stratigraphic units, which records the event history in a trench study, is directly affected by the sedimentation rate. Continuous sedimentation is always desired in trench studies; however, very fast sedimentation can cover event horizons with a thick pile of sediments, which prevent reaching the paleo-events.
- High water table usually prevents reaching deeper (older) stratigraphy.
- Logistics (i.e., permissions or environmental issues) may prevent excavating a perfect trench site, which is not ideally located or positioned.
- There may not be enough and suitable sampling material for dating based on environmental and/or sedimentary conditions.
- Measured displacements may also include post-seismic and/or creeping motions in addition to the coseismic slip.
- It is hard to identify all individual earthquakes along fast-moving faults (especially at overlapping sections of neighboring segments) due to limitation of dating methods.

Summary

In the developing world, mankind needs better life conditions, new settlements, and new industrial areas. It is well known that most part of the Earth's crust has a perpetual motion and that earthquakes are one of the most destructive natural hazards. Therefore, scientists have to find safe zones in which to live, especially at actively deformed regions, or provide information to mitigate against the seismic hazard. To achieve this, they have to know the exact location of the deformation zone and understand the characteristic behavior of the fault zone. Then, they can predict the future seismic risk of the area. Paleoseismological trenching is the most important tool to understand the nature of paleo-earthquakes and to predict the present and future behavioral characteristics of studied fault segments. The famous phrase of James Hutton "the present is the key to the past," then, can be improved to "the past is the key to the future" in the paleoseismic point of view. Of course, the term "past" covers mainly Holocene or Late Pleistocene, but not millions of years, while the term "future" embraces tens to thousands of years.

Trenching is a multidisciplinary study, including geology, geophysics, geomorphology, geoinformatics, geochronology, history, even mythology, etc. Pre-field, remote sensing studies provide important information on the location of the deformation zone and possible trench sites, which saves time, manpower, and budget. After the completion of desk and preliminary field studies, the first step is to find a convenient site for trenching. Important issues in proper location are continuous sedimentation, a low water table, presence of dating material, and sufficient logistic conditions (transportation, providing a work machine, etc.). Detailed geomorphological and geological maps are prepared to understand depositional or erosional conditions around trench sites. High-resolution micro-topographic maps give invaluable and precise information about effects of deformation and offset structures. Shallow geophysical methods are also important to

define exact deformation zone and the continuation of the fault in depth.

After deciding on the placement of the trench site, the orientation, size, and pattern of the excavation should be chosen based on scientific and logistic conditions. Safety precautions during and after excavation are very important both inside and outside of the trench. These precautions must be strictly applied until the closure of the trench. After excavation, the trench is prepared for a detailed study within the following steps: (1) The trench walls are cleaned and the traces of the work machine are removed; (2) the walls are put in a reference frame with vertical and horizontal lines (mainly by using a plastic string) in 1×1 or 0.5×0.5 m grids; and (3) stratigraphic horizons and critical structures are mapped onto squared paper scaled appropriately. Alternatively, systematic photographs and their photo-mosaics of trench walls can also be used for logging. Note that the identification of past (paleo-)earthquakes on trench walls needs careful, detailed, and accurate analyses of both exposed trench stratigraphy and structure. On-fault or off-fault deformation and structures (primary and/or secondary) are used to reveal seismic history of the studied fault segment. (4) Sample collection for dating of critical (event) horizons should be undertaken and is important in trench studies to model the timing of events and recurrence intervals. Finally, after the collection of all available data at the trench site, the excavated material is filled back carefully to restore the original environmental conditions as much as possible.

In conclusion, paleoseismological trenching, the direct observation method of historical earthquakes, provides both the exact location and history of the fault. Exposing faulted modern (or Holocene) sediments in suitable environments gives invaluable information about surface-rupturing earthquakes for a few hundreds to thousands of years. These paleoseismic data are very important in the planning of urban and industrial settlements and, most importantly, in providing a safer life for mankind.

Ancient earthquakes; Earthquake geology;
Paleoseismology; Prehistoric earthquakes

Introduction

The aim of paleoseismology is to generate a record of past earthquakes (i.e., magnitude, recurrence interval, timing, etc.) from a range of geological observables preserved within a landscape. This is achieved by identifying features associated with a single paleoearthquake as opposed to the long-term deformation along a fault or within a basin. As such paleoseismology has been defined as “the study of prehistoric earthquakes, their timing, location and size” (McCalpin and Nelson 2009) and as “the study of the ground effects from past earthquakes as preserved in the geologic and geomorphic record” (Michetti et al. 2005). The paleoseismic record provides information on the local and regional deformation accommodated by slip on faults as well as data on patterns of seismicity, which can inform hazard assessments for future earthquakes. In addition to providing information on past earthquakes, paleoseismology can also constrain models of fault behavior and enhance our understanding of the influence of active faulting in the landscape. So although paleoseismology is part of the broader field of earthquake geology, it is distinct and separate from modern instrumental seismology, tectonic and structural geology (including neotectonics), historical seismology, geodesy, and tectonic geomorphology. However, paleoseismology does involve aspects of many of these disciplines as well as elements from stratigraphy, sedimentology, quaternary geology, archeology, remote sensing, and geochronometry.

Paleoseismology began to be recognized as a scientific discipline during the 1970s in the United States and Japan. Although pioneers such as G. K. Gilbert in North America, A. McKay in New Zealand, and B. Koto in Japan made important early descriptions of fault scarps and earthquake ruptures, these studies made little attempt to relate features observed directly along faults to determine specific number or magnitude of earthquakes that had taken place. Prior to the 1970s, historical records represented the sole evidence used in the assessment of past earthquake activity. However, the use of

historical records to investigate past earthquakes is problematic in areas where records only exist for a couple of centuries, such as in North America, and where the return period of the fault is much larger than the period of data collection. Even in Europe and Asia where historical records can go back thousands of years, ambiguity can exist on the identity and location of the actual seismogenic fault and/or the earthquake rupture, as fault damage can be spread over large geographic areas. Historical records may also be incomplete due to low population densities in affected areas or political unrest resulting in events going unreported and can suffer a range of biases, such as conflation, amalgamation, or exaggeration of earthquakes, and deliberate or accidental misinformation (Rucker and Niemi 2010).

Paleoseismology, by contrast, is a scientific discipline whose studies identify and document a range of landscape features and excavate paleoseismic trenches, in order to understand and determine reliable earthquake magnitudes and recurrence intervals of prehistoric earthquakes, as well as correlating historical records to geological features along specific structures. It is important to note that the period of time that prehistory (prior to contemporary written accounts) encompasses will vary by location. The associated discipline of archeoseismology that seeks to supplement geological observations with archeological remains and evidence in the geoarcheological record can also complement the understanding of individual earthquakes in regions with long histories of human inhabitancy. However, circular reasoning needs to be avoided in these situations; for example, geological or archeological evidence is used to interpret an earthquake, which is dated with reference to an earthquake catalog and then ends up in such a catalog to be used to date future discoveries (Rucker and Niemi 2010).

Evidence for Paleoeearthquakes

Paleoseismic methods (paleoseismology) are used to investigate surface deformation and,

thus, independently increase the understanding of historical earthquakes. These methods include the application of the Environmental Seismic Intensity scale (ESI 2007), a scheme developed to quantify the intensity distribution of modern and historic earthquakes using the dimensions of the rupture (length, width, area, volume) and secondary features in the natural landscape (Michetti et al. 2007). However, for an earthquake to generate evidence that can be preserved at the surface, the magnitude of the earthquake must be large, generally considered to be $>6.5 M_w$ (moment magnitude) (McCalpin and Nelson 2009) or intensity VIII on the ESI 2007 scale (Michetti et al. 2007). Smaller earthquakes do not often cause sufficient surface deformation that can subsequently be preserved. This is not always the case though; for example, some large earthquakes that nucleate near the brittle-ductile transition [i.e., 1989 Loma Prieta $M 6.9$ (California) and 2001 $M_w 7.6$ Bhuj (India) earthquakes] have little or no surface expression (Yeats 2007). In contrast, some smaller earthquakes occasionally do cause surface rupture, such as in Sicily (Italy) where faults that generate $M_w 3.0$ – 5.0 earthquakes can produce surface faulting even during shallow events (Azzaro et al. 2000). Therefore, the local tectonic setting and regional stress regime should always be taken into account when undertaking paleoseismic studies.

The initial identification of potentially seismogenic faults through the identification of geomorphic features that form the “seismic landscape” is the first stage of a paleoseismic investigation (Michetti et al. 2005). A seismic landscape will have its topography, geology, and stratigraphy determined in part by the style of faulting, rate of tectonic activity, thickness, and rheology of the seismogenic layer; the prevailing climate is also critical since this controls rates of deposition and erosion that progressively shape geomorphic landforms over many seismic cycles. Thus, landscapes dominated by extensional faulting will exhibit features such as horsts and grabens and wind gaps on uplifted footwalls with triangular facets along the fault trace, whereas strike-slip faults will be characterized by features such as

shutter ridges, sag ponds, and offset or beheaded streams. Such assorted features can aid in the identification of faults both in the field and through the interrogation of satellite imagery, digital elevation models (DEMs), or aerial photographs. In turn, these features are often the focus of subsequent localized investigations such as geophysical surveys, paleoseismic ground investigation, or paleoseismic trenching.

A range of primary and secondary features can be associated with individual earthquakes and are used in paleoseismologic investigation once the active fault has been identified. Primary evidence forms instantaneously at the time of the earthquake due to slip along the fault plane and is therefore termed coseismic deformation. Secondary evidence can be caused by coseismic shaking or by subsequent (postseismic) erosion or deposition taking place at some time after the earthquake. Paleoseismic features can also be considered to be “on-fault” if along or near the fault or “off-fault” if they occur at some distance from the rupture. A further distinction can be made between geomorphic evidence and stratigraphic evidence of fault motion as observed in natural exposures and artificial paleoseismic trenches (McAlpin and Nelson 2009).

Typical examples of primary, on-fault evidence include: fault scarps, fissures, and folded, sheared, or displaced stratigraphic horizons (Table 1). Surface ruptures can be further divided into three categories: primary, subordinate, and sympathetic (Michetti 1994). Primary off-fault evidence can include tilted, uplifted, or submerged surfaces such as terraces (fluvial or coastal) or planation surfaces, drainage anomalies, change in coastal landforms, broken speleothems, and damage to man-made structures (both damage to ancient buildings and modern structures).

Secondary paleoseismic evidence consists of a great range of geomorphic and stratigraphic features including soft-sediment deformation, rock-falls, landslides, mud/sand volcanoes (also known as sand blows or boils), disturbed trees, and turbidite deposits, with little differentiation between the features that form on-fault and off-fault.

Paleoseismology, Table 1 Hierarchical classification of paleoseismic evidence with examples of stratigraphic and geomorphic features, modified from McCalpin and Nelson (2009)

Location	On-fault		Off-fault	
Timing	Coseismic	Postseismic	Coseismic	Postseismic
Primary paleoseismic evidence				
<i>Geomorphic features</i>	Surface ruptures	Colluvial aprons	Titled surfaces	Tectonic alluvial terraces
	1. Primary (i.e., fault scarps on main fault)	Afterslip modification to primary on-fault coseismic features	Uplifted shorelines	Afterslip modification to primary off-fault coseismic features
	2. Subordinate (ruptures branching from main fault)		Subsided shorelines	
	3. Sympathetic (ruptures on isolated faults)			
	Fissures			
	Folds			
	Mole tracks			
	Pressure ridges			
<i>Stratigraphic features</i>	Faulted strata	Scarp-derived colluvial wedges	Tsunami deposits and erosional unconformities caused by tsunamis	Erosional unconformities and deposits induced by uplift, subsidence, and tilting
	Folded strata	Fissure fills		
	Unconformities			
	Disconformities			
<i>Abundance of similar nonseismic features</i>	Few	Few	Some	Common
Secondary paleoseismic evidence				
<i>Geomorphic features</i>	Sand/mud volcanoes	Retrogressive landslides in the fault zone	Sand/mud volcanoes	Retrogressive landslides beyond the fault zone
	Landslides and lateral spreads in the fault zones		Landslides and lateral spreads beyond the fault zone	
	Disturbed trees and tree-throw craters		Disturbed trees and tree-throw craters	
			Fissures and Sackungen	
<i>Stratigraphic features</i>	Sand dykes and sills	Sediments deposited from retrogressive landslides	Sand dykes	Erosion or deposition in response to landscape disturbance (i.e., landslides, fissures, etc.)
	Soft-sediment deformation		Filled craters	
	Landslide toe thrusts		Soft-sediment deformation	
			Turbidites	
			Tsunamiites	
<i>Abundance of similar nonseismic features</i>	Some	Very common	Some	Very common

It should be noted that the distinction between primary and secondary off-fault evidence can be difficult to determine as seismic shaking may generate features that continue to evolve after the cessation of the earthquake. Furthermore, some features could represent both primary and secondary evidence. Tsunami deposits, for example, could be considered as primary evidence where the tsunami is produced directly by primary fault displacement, but could also be considered secondary evidence if say a landslide is triggered by earthquake shaking in a coastal location subsequently resulting in a tsunami. Secondary features are also more ambiguous than primary evidence as other geological mechanisms can result in their formation. McCalpin and Nelson (2009) used these classifications to define 16 categories (Table 1) of paleoseismic evidence that can commonly be distinguished in either geomorphic landforms or in the stratigraphic record. Therefore, using a combination of different lines of paleoseismic evidence tends to produce the most robust results in paleoseismic studies. As on-fault evidence often is clearer but provides little evidence of the strength of shaking or spatial extent of ground deformation, by contrast, geomorphic evidence can be preserved over wide areas, providing this spatial dimension to earthquake studies, yet it can be difficult to find the source of these off-fault features and age control may be lacking due to an absence of datable material.

As a result many paleoseismic studies focus on the excavation of trenches across faults, exposing offset and deformed strata resulting from seismogenic faulting. However, paleoseismic trenching studies commonly only take place at a few sites restricting the lateral applicability of the results. Crucially, these ground investigations can produce critical age control mainly through the use of radiocarbon dating or increasingly the application of optically stimulated luminescence (OSL) dating from material in offset stratigraphic horizons. It must also be noted that geological processes unrelated to earthquake faulting can produce features similar to coseismic and postseismic landforms and deposits and that erosion and sedimentation

subsequent to an earthquake will act to modify and conceal the effects of surface faulting.

Seismic Hazard Assessments from Paleoseismology

The main goal of paleoseismic studies is to determine the dimensions, magnitude, and timing of past earthquakes and the slip rate on seismic faults to inform deterministic or probabilistic seismic hazard assessments (SHAs) and seismic risk assessments. The most common way of determining the magnitude of past earthquakes is to use primary and secondary evidence to determine the surface rupture length of the past event and the amount of displacement (maximum or average slip) that occurred. These parameters can then be compared to worldwide catalogs of historical earthquakes and rupture lengths to calculate the probable magnitude of the paleoearthquake (Wells and Coppersmith 1994). Similarly, evidence for the area of displacement on a fault, or the seismic moment, can be used to estimate the magnitude of paleoearthquakes. However, these methods produce uncertain results due to the complex nature of faulting and the widespread use of global relationships that might not hold true on a regional scale. By contrast, spatial distributions of secondary evidence may reveal patterns of ground motion intensity that can be used to infer earthquake magnitudes. These observations can be used in a framework to determine the relative intensity of an earthquake, such as the ESI 2007 scale that combines observations of primary and secondary evidence on a scale of I–XII, with earthquakes intensity IV and above producing observable ground deformation of increasing severity (Michetti et al. 2007).

There are a number of problems with this approach. One is that primary and secondary features of the same age (within error) observed in a stratigraphic or geomorphic context are assumed to be the result of a single earthquake. However, earthquakes are observed to often cluster in time and space, and such earthquake sequences cannot be easily separated in the geological record due to the uncertainties in dating

methods resulting in an overestimation of the earthquake magnitude. Displacement is also not constant along the strike of the fault, going from zero displacement at the fault tips to a maximum near the center, which is often modeled as a symmetrical profile in seismic hazard assessment but could be an irregular shape – this could lead to bias in displacement reconstructions.

The earthquake recurrence interval (the time elapsed between any two paleoearthquakes) on a fault is also a key component of characterizing the seismic hazard. Faults that rupture over long recurrence intervals in larger events can be less hazardous than faults that rupture more frequently in moderate events, as the likelihood of impacting a critical facility is lower for the long return earthquake. Recurrence intervals can be calculated in one of two ways. The less preferred way is to calculate the average recurrence interval over multiple paleoearthquakes, a method commonly used in neotectonic studies. The preferred alternative is to individually date each paleoearthquake “event horizon” to determine the actual time between each earthquake. It is important to appreciate that the time since the last earthquake on a fault (the elapsed time) does not represent a recurrence interval because it does not bound two earthquakes. Also, when determining recurrence intervals, it is important to assess the degree of underrepresentation or overrepresentation in the seismic record (McCalpin and Nelson 2009). Underrepresentation results from an incomplete preservation record as a result of numerous factors that can affect the potential for preservation in a site as well as subsequent tectonic activity obscuring earlier events. The contrasting issue of overrepresentation is less often considered but can occur when nonseismic features are interpreted as coseismic or postseismic evidence. Overrepresentation can also occur if the paleoseismic record is well preserved during a period of earthquake clustering, which in turn is extrapolated over longer periods and thereby leads to an erroneously large number of past earthquakes being inferred (McCalpin and Nelson 2009). Therefore, it is important to consider the length of the window of observation and compare short-term slip

rates with the long-term average to assess the applicability of results.

Fault slip rate is the displacement of the fault over time and, as implied above, can apparently differ when considered at different timescales. The true slip rate is that considered over one or more closed (i.e., complete) seismic cycles, whereas an apparent slip rate is obtained if the slip rate is calculated over a time period containing complete and incomplete seismic cycles. However, due to variations in the displacement and time span between earthquakes, these measurements normally indicate that the slip rate varies between earthquake cycles and can be much higher than the long-term average during earthquake clustering or much lower during periods of fault quiescence.

These various parameters of fault and earthquake behavior can then be used to undertake seismic hazard assessments (SHAs); there are two main types of SHAs, deterministic seismic hazard assessment and probabilistic seismic hazard assessment.

Deterministic Seismic Hazard Assessment

Deterministic seismic hazard assessments (DSHAs) calculate the worst-case scenario for a site using the maximum potential magnitude for the largest active fault (the “controlling fault”) and the distance from that fault to the site in question as two parameters that combine (using an attenuation equation) to determine the potential ground motion at any point from the fault. The method also requires knowledge of the rock or soil properties at the site. Yet, DSHAs do not take into account the time probability of an earthquake occurring during the life time of the facility, so data on the recurrence interval and slip rate on the controlling fault is irrelevant.

Probabilistic Seismic Hazard Assessment

Probabilistic seismic hazard assessments (PSHAs), by contrast, calculate the worst seismic effects for a site using both the time-independent factors (magnitude and distance) used in DSHA combined with the time-dependent factors of slip rate and recurrence interval for the controlling fault. Therefore, this method determines both

the probability of an earthquake or earthquakes occurring near the critical facility within a defined time period (normally related to the design life of the facility) and also what the effects of these earthquakes would be on the facility. Currently, PSHA is the most commonly used method having generally replaced DSHA for most facilities.

Summary

Paleoseismology seeks to identify and appraise prehistoric or pre-instrumental earthquakes through the observation, documentation, and interpretation of geomorphic and stratigraphic evidence formed on, or near, earthquake ruptures as a result of primary rupture or secondary shaking. Such investigations have greatly improved our understanding of seismogenic fault behavior, revealing the segmentation of major faults (i.e., Schwartz and Coppersmith 1984), the temporal clustering of earthquakes in a nonperiodic fashion, the scaling relations between earthquake recurrence intervals and fault slip rates, and the tendency for faults to have characteristic rupture patterns (i.e., amount of slip: rupture length, magnitude). Of course, paleoseismological studies have also revealed periodic, nonscalar, and noncharacteristic earthquake faults and rigorous field studies are needed to test these apparent conflicting relationships. Variables determined from paleoearthquake studies (magnitude, slip, recurrence intervals) can be used to undertake seismic hazard assessments (SHA), either as a deterministic approach to calculate the worst-case scenario or a probabilistic approach to calculate the probability of an earthquake of a given size occurring within a given time period. However, since many paleoseismic data sets are too incomplete to precisely estimate fault slip rates or recurrence intervals, the contribution of paleoseismology to seismic hazard remains inaccurate (Grant 2002). Refining the record of past earthquakes is crucial for the improvement of earthquake-related hazard (seismic, tsunami, landslide, etc.) assessments for urban planning and critical facilities (i.e., nuclear power stations,

dams, chemical/petroleum facilities). Because even in well-constrained areas, lessons can still be learned by refining historical data with geological observations, as witnessed by the 2011 Tohoku (Japan) earthquake, where geological evidence of past megathrust earthquakes was available but not integrated into the existing hazard planning (Silva et al. 2011).

Paleoseismology and Landslides

Randall W. Jibson
U.S. Geological Survey, Golden, CO, USA

Synonyms

Earthquake-triggered landslides; Seismic ground failure; Slope-stability analysis

Introduction

Most moderate to large earthquakes trigger landslides (Fig. 1). In many environments, landslides preserved in the geologic record can be analyzed

Paleoseismology and Landslides, Fig. 1 Madison Canyon landslide, triggered by the 1959 Hebgen Lake, Montana, earthquake (M_w 7.1). Strong shaking caused $28 \times 10^6 \text{ m}^3$ of rock to slide into the canyon, which dammed the river and created a lake more than 60 m deep. Slide scar at left is 400 m high, debris is as thick as 67 m in valley axis, and slide debris traveled 130 m up the right valley wall. Twenty-eight people were killed by the slide (Photograph courtesy of J.R. Stacy, U.S. Geological Survey Photographic Library, photo no. 209a)

to determine the likelihood of seismic triggering. If evidence indicates that a seismic origin is likely for a landslide or group of landslides, and if the landslides can be dated, then a paleoearthquake can be inferred, and some of its characteristics can be estimated. Such paleoseismic landslide studies thus can help reconstruct the seismic shaking history of a site or region (Jibson 2009).

Paleoseismic landslide studies differ fundamentally from paleoseismic fault studies. Whereas fault studies seek to characterize the movement history of a specific fault, landslide studies characterize the shaking history of a site or region irrespective of the earthquake source. In regions that contain multiple seismic sources and in regions where surface faulting (► [Seismic Actions due to Near-Fault Ground Motion](#)) is absent, paleoseismic ground-failure studies thus can be valuable tools in hazard and risk studies that are more concerned with shaking hazards

than with interpretation of the movement histories of individual faults. In fact, paleoseismic studies in some parts of the world typically rely more on ground failure than on surface fault ruptures.

The practical lower bound earthquake that can be interpreted from paleoseismic landslide investigations is about magnitude 5–6 (► [Earthquake Magnitude Estimation](#)). This range is comparable or perhaps slightly lower than that for paleoseismic fault studies. Obviously, however, larger earthquakes tend to leave much more abundant and widespread evidence of landsliding than smaller earthquakes; thus, available evidence and confidence in interpretation increase with earthquake size.

Paleoseismic landslide analysis involves three steps: (1) identify a feature as a landslide, (2) date the landslide, and (3) determine if the landslide was triggered by earthquake shaking. This article addresses each of these steps and discusses methods for interpreting the results of such studies. Only subaerial landslides are discussed here; submarine landslides are analyzed using different methods.

In this article, *landslide* is used as a generic term to include all types of downslope movement of earth material, including types of movement that involve little or no true sliding. Thus, rock falls, debris flows, etc., are considered types of landslides. The classification system of Varnes (1978) is used, which categorizes landslides by the type of material involved (soil or rock) and by the type of movement (falls, topples, slides, slumps, flows, or spreads). Other modifiers commonly are used to indicate velocity of movement, degree of internal disruption, state of activity, and moisture content.

Identifying Landslides

Identifying surface features as landslides can be relatively easy for fairly recent, well-developed, simple landslides. Older, more degraded landslides or those having complex or unusual morphologies can be more difficult to identify. In general, landslides are identified by anomalous

Paleoseismology and Landslides, Table 1 Relative abundance of earthquake-induced landslides

Abundance	Landslide type
Very abundant	Rock falls
	Disrupted soil slides
	Rock slides
Abundant	Soil lateral spreads
	Soil slumps
	Soil block slides
	Soil avalanches
Moderately common	Soil falls
	Rapid soil flows
	Rock slumps
Uncommon	Subaqueous landslides
	Slow earth flows
	Rock block slides
	Rock avalanches

Note: Data from Keefer (1984). Landslide types use nomenclature of Varnes (1978) and are listed in decreasing order of abundance

topography, including arcuate or linear scarps, backward-rotated masses, benched or hummocky topography, bulging toes, and ponded or deranged drainage. Abnormal vegetation type and age also are common.

Earthquakes can trigger all types of landslides, and all types of landslides triggered by earthquakes also can occur without seismic triggering. Therefore, an earthquake origin cannot be determined solely on the basis of landslide type. However, some types of landslides tend to be much more abundant in earthquakes than other types. Table 1 shows the relative abundance of various types of earthquake-triggered landslides. Overall, the more disrupted types of landslides are much more abundant than the more coherent types of landslides. Also, most earthquake-induced landslides occur in intact materials rather than in preexisting landslide deposits; thus, the number of reactivated landslides is small compared to the total number of landslides triggered by earthquakes. Earthquake-triggered landslides most commonly occur in materials that are weathered, sheared, intensely fractured or jointed, or saturated.

Sackungen (ridge-crest troughs) are a somewhat controversial type of ground failure that has been related, in some cases, to seismic

shaking. Sackungen are identified by one or more of the following: (1) grabens or troughs near and parallel to ridge crests of high mountains, (2) uphill-facing scarps a few meters high that parallel the topography, (3) double-crested ridges, and (4) bulging lower parts of slopes.

Determining Landslide Ages

Paleoseismic interpretation requires establishing the numerical age of a paleoearthquake. In the case of earthquake-triggered landslides, this means that dating landslide movement is required. Several methods for dating landslide movement can be used; some are similar or identical to those used for dating fault scarps, while others are unique to landslides.

Different types of landslides could be datable by different methods, depending on a variety of factors such as distance of movement, degree of internal disruption, landslide geometry, type of landslide material, type and density of vegetation, and local climate. Ideally, multiple, independent dating methods should be used to increase the level of certainty of the age of landslide movement.

Historical Methods

Some old landslides might have been noted by local inhabitants or could have damaged or destroyed human works or natural features. In some parts of the world, potentially useful historical records or human works extend back several hundreds or thousands of years. For fairly recent events, comparing successive generations of topographic maps or aerial photographs can bracket the time period in which mappable landslides first appeared.

Dendrochronology

Dendrochronology can be applied to date landslide movement in several ways. At the simplest level, the oldest undisturbed trees on disrupted or rotated parts of landslides should yield reasonable minimum ages for movement. On rotational slides that remained fairly coherent, preexisting trees that survived the sliding will have been

tilted because of headward rotation of the ground surface; if both tilted and straight trees are present on such landslides, the age of slide movement is bracketed between the age of the oldest straight trees and the youngest tilted trees. Using this simple application of dendrochronology to date coherent translational slides is more difficult because trees can remain upright and intact even after landslide movement. On all types of landslides, trees growing from the surface of the scarp will yield minimum ages of scarp formation, from which the age of slide movement can be interpreted. In some cases, trees killed by landslide movement will be preserved and can thus yield the exact date of movement.

A more sophisticated application of dendrochronology involves quantitative analysis of growth rings. For trees that have survived one or more episodes of landslide movement, such analysis can be used to identify and date reaction wood (eccentric growth rings), growth suppression, and corrosion scars, which might be evidence of landslide movement. Some landslides block stream drainages and form dams that impound ponds or lakes. Inundation of areas upstream from landslide dams can drown trees that can be dated dendrochronologically.

Radiometric and Cosmogenic Dating

Radiometric dating ([► Radiocarbon Dating in Paleoseismology](#)) (most commonly using ^{14}C) can be used in a variety of ways to date organic material buried by landslide movement. Landslide scarps degrade similarly to fault scarps, and so colluvial wedges at the bases of landslide scarps might contain organic material that can be retrieved by trenching or coring and dated radiometrically. Fissures on the body of a landslide, particularly near the head where extension can take place, also can trap and preserve organic matter. If the landslide mass is highly disrupted, as in rock or soil falls or avalanches, then some vegetation from the original ground surface might have become mixed with the slide debris; such organic material excavated from slide debris can be dated radiometrically. At the toes of landslides, slide material commonly is deposited onto undisturbed ground; if this original ground

surface can be excavated beneath the toe of a slide, buried organic material from this surface can be dated to indicate the age of initial movement.

Sag ponds commonly form on landslides, and organic material deposited in such ponds can be dated radiometrically. Organics at the base of the pond deposits should yield reliable dates of pond formation.

Vegetation submerged from inundation of areas upstream from landslide dams also can be dated radiometrically. Similarly, landslides into lakes can submerge and kill vegetation that can be dated.

Rock-fall and rock-avalanche deposits can be dated cosmogenically (► [Luminescence Dating in Paleoseismology](#)) if the surface of the deposit has been relatively stable since the time of emplacement. This method measures the amount of time that specific types of mineral grains have been exposed to cosmic radiation. The assumption is that a significant proportion of the material on the surface of a rock-fall or rock-avalanche deposit was newly fractured and exposed when the landslide occurred.

Lichenometry

Lichenometry – analysis of the age of lichens based on their size – can be used to date rock-fall and rock-avalanche deposits. By measuring lichen diameters on rock faces freshly exposed at the time of failure, numerical ages can be estimated by assuming that lichens colonized the rock face in the first year after exposure. Because rock-fall and rock-avalanche deposits typically include abundant rocks having freshly exposed faces, numerous samples generally can be taken to create a database for the statistical analysis required by lichenometry. Lichenometric ages must be calibrated at sites of known historical age or by comparison with other numerical dating techniques. Lichenometric dating is subject to considerable uncertainty, however, because several decades can elapse before lichens colonize a fresh rock exposure, and lichens might never colonize unstable landslide deposits on very steep slopes.

Weathering Rinds

For a given climate and rock type, measuring the thickness of weathering rinds can be used to date when rocks were first exposed at the ground surface. For rock falls and rock avalanches and for other landslides whose movement exposed rock fragments at the ground surface, measuring the thickness of weathering rinds can be used to date landslide movement. Determining which rock surfaces were initially exposed at the time of landsliding can be difficult, but if a sufficiently large number of samples can be measured, consistent statistical results of predominant ages that relate to landslide movement can be obtained.

Pollen Analysis

Analysis of pollen in deposits filling depressions on landslides can yield both an estimated age of initial movement and, in some cases, a movement history through time. Such analyses assume that sediment deposition and incorporation of pollen occur immediately following landslide movement and that local climatic and vegetation variations can be accounted for. Pollen samples from the buried ground surface beneath the toes of landslides also have potential for use in dating landslide movement.

Geomorphic Analysis

Landslides are disequilibrium landforms that change through time more rapidly than surrounding terrain. By analyzing the degree of degradation of landslide features such as scarps, ridges, sags, and toes, relative ages can be assigned to various landslides. Criteria for such relative age classification might include degree of definition of landslide features, soil development, tephra cover, stream dissection, preservation of vegetation killed by movement, and drainage integration.

Models of fault-scarp degradation also have potential application in landslide dating because landslide scarps should behave similarly to fault scarps. Several approaches to morphologic fault-scarp dating have been proposed, all of which require calibration for various parameters such as climate and scarp material. Scarp degradation commonly is modeled as a diffusion process, in

which degradation rate varies in time and is a function of slope angle, which represents the degree to which the scarp is out of equilibrium with the surrounding landscape.

Analysis of soil-profile development also is a potential tool for dating landslides. New soil profiles will begin to develop on disrupted landslide surfaces. If such surfaces can be identified, dating the newly developed soil profile will indicate the age of movement.

Interpreting an Earthquake Origin for Landslides

Interpreting an earthquake origin for a landslide or group of landslides is by far the most difficult step in the process, and methods and levels of confidence in the resulting interpretation vary widely. This section summarizes several basic approaches that can be used to interpret the seismic origin of landslides.

Regional Analysis of Landslides

Many paleoseismic landslide studies involve analysis of large groups of landslides rather than individual features. The premise of these regional analyses is that a group of landslides of the same age, scattered across a discrete area, probably was triggered by a single event of regional extent. In an active seismic zone, that event commonly is inferred to be an earthquake. Such an interpretation could be justified in areas where landslide types and distributions from historical earthquakes have been documented and can be used as a standard for comparison. In areas where such historical observations are absent, assuming an earthquake origin for landslides of synchronous age is much more tenuous, primarily because large storms also can trigger widespread landslides having identical ages and spatial distributions.

Differentiating between such groups of storm- and earthquake-triggered landslides might be possible using a statistical approach to characterize the distribution of steep slopes in a region. Storm-triggered landslides form most commonly near the bases of slopes and thus tend to form

landscapes characterized by steep inner gorges. Earthquake-triggered landslides, on the other hand, tend to form either near ridge crests or more uniformly across the entire reach of slopes; corresponding landscapes generally lack well-developed inner gorges. These landscape patterns provide supportive evidence of the possible seismic origin of landslides in a region, but they cannot be used to definitively determine the origin of any specific landslide.

Some criteria to support a seismic origin for landslides include (1) ongoing seismicity in the region that has triggered landslides; (2) coincidence of landslide distribution with an active fault or seismic zone; (3) geotechnical slope-stability analyses showing that earthquake shaking would have been required to induce slope failure (discussed in detail subsequently); (4) presence of liquefaction features associated with the landslides; (5) correlation between the elongation of a landslide distribution and the location and dimensions of the seismogenic faults in a region; and (6) landslide distribution that cannot be explained solely on the basis of geologic or geomorphic conditions. Obviously, the more of these criteria that are satisfied, the stronger the case for seismic origin.

Landslide Morphology

Some landslides have morphologies that strongly suggest triggering by earthquake shaking. For example, stability analyses of landslides on low-angle basal shear surfaces show that they generally form much more readily under the influence of earthquake shaking than in other conditions. Landslides that formed as a result of liquefaction of subsurface layers also are much more likely to have formed seismically than aseismically. Slides that form as a result of intense rainfall are more fluid and tend to spread out more across a depositional area, whereas seismically induced landslides tend to have a blockier appearance and a more limited depositional extent in some cases. None of these criteria is definitive, but the types and characteristics of landslides described previously do suggest seismic triggering and can be used as corroborative evidence of earthquake triggering.

Landslide size is considered evidence of seismic triggering in some cases. In areas where large landslides have been documented in historical time to occur only during earthquakes, the large size of prehistoric landslides could suggest seismic origin and could even be used to infer the relative size of the triggering earthquake; very large landslides commonly are triggered by longer duration and longer period shaking, which generally relate to larger magnitude earthquakes.

Multiple lines of evidence strengthen an argument for seismic triggering. For example, a large, ancient landslide near an active fault and having a low-angle basal shear surface might be considered a strong candidate for having been seismically triggered, particularly if similar landslides have been documented in recent earthquakes.

Sackungen

Sackungen are geomorphic features in mountainous areas that are characterized by ridge-parallel, uphill-facing scarps; double ridge lines; and troughs or closed depressions along ridge crests. While topography and gravity clearly influence the ridge-parallel geometry of sackungen, several different processes for their origin have been proposed, including gravitational spreading due to long-term creep, stress relief due to deglaciation, faulting, strong shaking, or a combination of factors. It appears that sackungen can form under a variety of conditions or combinations of conditions because sackungen have been documented to have formed in different ways in different tectonic and geologic settings.

Sackungen have been documented in several historical earthquakes, but the specific mechanism by which they form appears to be complex. Strong shaking certainly plays a role, but in many cases sackungen formed in the immediate vicinity of, and parallel to, the seismogenic faults, which suggests that fault-related tectonic deformation as well as strong shaking might contribute to their formation. And some sackungen appear to have multiple episodes of movement, some related to seismic shaking and some to periods of climatically induced increased groundwater levels.

Because sackungen can form in a variety of tectonic and geologic environments and can form by several different processes, paleoseismic interpretation is difficult and commonly tenuous. Criteria for establishing the seismic or nonseismic origin of sackungen have been proposed with the aim of differentiating between features indicating abrupt, episodic movement versus those indicating gradual, continuous movement. McCalpin (1999) proposed seven criteria, including stratigraphic, geomorphic, and structural evidence, to differentiate between seismic and nonseismic movement: (1) evidence of continuous deformation of sediments suggests a nonseismic origin; (2) sackung deformation events that are contemporaneous with other regional paleoseismic features could be coseismic; (3) if sackungen overlie a steeply dipping crustal fault zone that has a net displacement much larger than the scarp height, the fault could be active; (4) gravity-driven sackungen tend to occur in swarms and be shorter, less continuous, and arcuate, whereas tectonic scarps tend to be longer, more continuous, singular, and straighter; (5) height-to-length ratios of gravity-driven sackungen are much greater than those of tectonic faults; (6) an asymmetrical fault zone having a sharp upper boundary and transitional brecciated lower boundary is more likely to be a sackung than a tectonic fault; and (7) subsurface deformation zones of tectonic faults can occur in any spatial relation with the modern topography, whereas subsurface deformation zones of sackungen are closely related to modern topography.

No single criterion is sufficient to unequivocally prove the seismic or aseismic origin of a sackung feature. And a seismic origin could have resulted from strong shaking, primary tectonic faulting, sympathetic faulting on a feature other than the seismogenic fault, or a combination of these factors. Also, a single sackung feature could have had both seismic and aseismic episodes of movement. Therefore, paleoseismic interpretation of sackungen is generally quite challenging and in many cases impossible. In some cases, however, evidence for abrupt episodes of movement that can be linked to seismic event can provide valuable paleoseismic evidence.

Sediment from Earthquake-Triggered Landslides

Earthquake-triggered landslides can profoundly affect alluvial systems by denuding slopes, which generates large amounts of disrupted sediment that will move into the alluvial system and physically disrupt drainage systems. The commonest types of landslides triggered by earthquakes are shallow, highly disrupted slides in unconsolidated surficial material, and the deposits of these types of landslides tend to move quickly into stream drainages. Thus, earthquakes can deposit large pulses of sediment into alluvial systems, which can (1) create new alluvial fans, (2) cause widespread aggradation of channels, (3) provide material for subsequent deposition on fan surfaces by debris flows and hyperconcentrated flows, and (4) affect the overall development of the fan surface on the long term. Thus, landslides triggered by earthquakes can leave evidence in the depositional record of alluvial systems.

Large earthquakes can cause a spectrum of ground-failure effects including abundant landslides, pervasive ground cracking, microfracturing of surficial hillslope materials, collapse of drainage banks over long stretches, widening of hillside rills, and lengthening of first-order tributary channels. Such widespread disruption increases the capacity of channels to carry runoff by enlarging upstream channels and detaches large amounts of loose slope material, which increases the amount of sediment available for transport and deposition.

Comparison of normal debris-flow deposits to those deposited soon after major earthquakes shows that the post-earthquake deposits tend to (1) be abnormally thicker, (2) contain larger clasts, (3) contain a higher percentage of coarse clasts, and (4) have more angular clasts.

Landslides that Straddle Faults

Landslides sometimes occur on slopes immediately above fault traces, and the slide mass can extend across the trace. Subsequent surface movement of such a fault would offset the landslide mass and allow estimation of fault slip rates if the slide could be dated. This approach does not

require that the landslide be seismically triggered because the paleoseismic interpretation is based on post-landslide fault offset of the landslide mass. However, landslides triggered in the immediate vicinity of active faults commonly are seismically triggered.

Precariously Balanced Rocks

Precariously balanced rocks have been used as crude paleoseismoscopes. The premise of this approach is that areas containing precariously balanced rocks indicate the absence of strong earthquake motions since the precarious rocks developed; paleoseismic interpretations can be made by estimating the peak accelerations required to cause toppling and the length of time the rocks have been precarious. The shaking required to topple precarious rocks has been estimated using analytical and numerical modeling, physical modeling using shaking-table tests, and field experiments on actual precarious rocks. Precarious rocks have been defined as being capable of being toppled by peak accelerations of 0.1–0.3 g; rocks requiring 0.3–0.5 g are commonly defined as semi-precarious. Precarious rocks can be dated cosmogenically and by analysis of rock-varnish microlaminations.

Results from precarious-rock analyses are not always consistent with other lines of paleoseismic evidence. There are several possible reasons for these inconsistencies, and no consensus currently exists regarding the validity of the results of the precarious-rock studies. Therefore, several caveats regarding precarious-rock studies should be kept in mind: (1) Large uncertainties exist in the required toppling accelerations owing both to the geometric complexity of the rocks and the complexities of 3-D ground motion. (2) Not all precarious rocks in a given area will be toppled by the estimated threshold ground shaking. Studies of overturning of tombstones in Japan have shown that a given threshold acceleration will overturn only a fraction of a group of seemingly identical tombstones. Therefore, finding some precarious rocks in an area does not necessarily mean that the area has not experienced the threshold ground shaking. (3) Establishing the age of precarious rocks does

not necessarily determine the minimum time since a certain level of shaking has occurred because the toppling acceleration of a given rock will have been continuously changing as the rock has evolved into a precarious state. For example, a precarious rock with an estimated age of 20 ka and a present-day toppling acceleration of 0.2 g might have had a toppling acceleration of 1.0 g at 20 ka, 0.5 g 10 ka, etc.; therefore, it cannot be concluded that the present-day toppling acceleration has not been exceeded in 20 ka.

Speleoseismology

Speleoseismology is the investigation of earthquake records in caves. Such records can include broken speleothems (stalactites, stalagmites, soda straws, etc.), cave-sediment deformation structures, offset along fractures and bedding planes, simple rock falls (incision), and coseismic fault displacement. Before an earthquake origin can be inferred, all other possible causes of the disturbance must be ruled out. Such causes include human or animal disturbance, water flow, ice movement, debris flow, and sediment creep.

By measuring and dating the tilting and collapse of many stalagmites in a region, it is possible to differentiate sudden (seismic) versus gradual movements and local versus regional causes. Tilting and collapse events can be dated by analysis of radiometrically determined speleothem growth rates; uranium-series isotopes can be analyzed to date speleothems precisely within the 0–500 ka range. By modeling stalagmites as simple inverted pendulums, it is possible to estimate the minimum ground shaking necessary to cause collapse using pseudostatic engineering analysis.

Numerical and physical models have been developed to examine the ground shaking that would be required to break and topple various types of speleothems. These models have been used to measure the natural frequencies and damping characteristics of speleothems and the peak ground accelerations necessary to break them. The natural frequencies of most speleothems are between 50 and 700 Hz, well above the range of seismically generated ground

motion (0.1–30 Hz). The only exceptions are so-called soda straws: long, slender speleothems that can have natural frequencies as low as 20 Hz. Most speleothems would require ground accelerations in excess of 1 g to cause breakage; some very long, thin soda straws, however, could be broken at accelerations as low as 0.1–0.2 g. Thus it appears that only exceptionally long, thin speleothems having weak sections are likely to break during earthquakes, and only about 2 % of such structures have been observed to have broken in recent, well-documented earthquakes.

Summary

Many methods for interpreting the seismic origin of landslides have been developed and, in some cases, successfully applied to paleoseismic analysis. Virtually all of the methods summarized in this section have one aspect in common, which is stated explicitly in most papers: the seismic origin of the features being interpreted remains tentative and cannot be proven, because in each case a nonseismic process could have produced the observed features. Circumstantial evidence for seismic triggering ranges from very strong to extremely tenuous. Indeed, on the latter end of the spectrum, the reasoning can be rather circular: an earthquake origin for a feature is assumed, and then an earthquake origin is interpreted and concluded from analysis of that feature. Any paleoseismic interpretation of a feature is limited primarily by the certainty with which seismic triggering can be established.

Using Stability Analysis to Determine Seismic Landslide Origin

The most direct way to assess the relative likelihood of seismic versus aseismic triggering of an individual landslide is to apply established methods of static and dynamic slope-stability analysis (Jibson and Keefer 1993). Such an analysis involves constructing a detailed slope-stability model of static conditions to determine if failure is likely to have occurred in any reasonable set of groundwater and shear-strength conditions in the absence of earthquake shaking.

All potential nonseismic factors must be considered; these might include processes such as fluvial or coastal erosion that oversteepens the slope or undrained failure resulting from rapid draw-down (for slopes subject to submersion). If aseismic failure can reasonably be excluded even in worst-case conditions (minimum shear strength, maximum piezometric head), then an earthquake origin can be inferred. Dynamic slope-stability analyses can then be used to estimate the minimum shaking conditions that would have been required to cause failure.

This approach is by far the most involved but also yields quantitative results that can be used to assess landslide origins (Jibson and Keefer 1993). Steps involved in a typical stability analysis are summarized in the following sections.

Geotechnical Investigation

Accurately modeling the stability of a slope requires detailed investigation to determine the geotechnical properties of the slope materials. The key properties required for a stability analysis include the material shear strength (friction angle and cohesion), unit weight, and moisture content. Investigating these properties might involve (1) in situ approaches such as cone-penetration testing or (2) acquiring samples that can be tested in the laboratory.

Shear strength can be characterized in different ways to model different types of failure conditions. In aseismic conditions, effective (drained) shear strengths are used because pore-water pressures are assumed to be in static equilibrium. During earthquakes, many soils behave in a so-called undrained manner because excess pore pressures induced by the transient ground deformation cannot dissipate during the brief duration of the shaking; therefore, total (undrained) shear strengths are used to model seismic failure conditions. Effective shear strengths can be measured in the laboratory using various methods: (1) direct shear in which the strain rate is slow enough to allow full drainage and (2) consolidated-undrained triaxial (CUTX) shear in which pore pressure is measured to allow modeling of drained conditions. Total (undrained) shear strength can be measured

using CUTX shear tests or simpler methods such as vane shear.

Static (Aseismic) Slope-Stability Analysis

Static slope-stability analysis models the stability of slopes in the absence of earthquake shaking. A stability model using effective shear strengths can be constructed, and the worst possible groundwater conditions can be modeled to determine the likelihood of aseismic failure. If a slope is stable even in worst-case aseismic conditions, then it is likely that seismic shaking was necessary to induce failure.

Slope stability is quantified using the factor of safety (FS), the ratio of the sum of the resisting forces or moments that act to inhibit slope movement to the sum of the driving forces or moments that tend to cause movement. Slopes having factors of safety greater than 1.0 are thus stable; those having factors of safety less than 1.0 should move. Of course, input parameters have uncertainties, and so determining the stability of slopes from the factor of safety requires judgment. A good rule of thumb for interpreting factors of safety for slopes that have well-constrained input parameters is as follows:

FS < 1 is considered unstable.

FS = 1.00–1.25 is considered marginally stable.

FS = 1.25–1.50 is considered stable.

FS > 1.50 is considered very stable.

Dynamic (Seismic) Slope-Stability Analysis

Analysis of slope stability during earthquake shaking is best modeled using sliding-block analysis. This type of analysis was first introduced by Newmark (1965) and is used widely in engineering practice. Newmark's method models a landslide as a rigid-plastic friction block that slides on an inclined plane. The block begins to slide when a given critical (or yield) base acceleration is exceeded; thus, critical acceleration is defined as the base acceleration required to overcome basal shear resistance and initiate sliding. The analysis calculates the cumulative permanent displacement of the block as it is subjected to the effects of an earthquake acceleration-time history, and the user judges the significance of the

displacement. Laboratory model tests and analysis of actual earthquake-induced landslides have confirmed that Newmark's method can fairly accurately predict landslide displacements if slope geometry and soil properties are known accurately and if earthquake ground accelerations can be estimated using real or artificial acceleration-time histories. More sophisticated forms of sliding-block analysis have been developed that allow modeling the landslide block as a flexible rather than a rigid mass, which yields more accurate results for deeper, larger landslides.

The critical acceleration is a simple function of the static factor of safety and the landslide geometry; it can be expressed as

$$a_c = (FS - 1)g \sin \alpha, \quad (1)$$

where a_c is the critical acceleration in terms of g , the acceleration of Earth's gravity; FS is the static factor of safety; and α is the thrust angle, the angle from the horizontal that the center of mass of the potential landslide block first moves.

Calculation of the estimated landslide displacement consists of a two-part integration with respect to time: (1) the parts of the selected acceleration-time history that lie above the critical acceleration of the landslide block are integrated to yield the velocity of the block with respect to its base and (2) the velocity curve is then integrated to determine the cumulative permanent displacement of the block.

Conducting a rigorous sliding-block analysis requires knowing the critical acceleration of the landslide and selecting one or more earthquake acceleration-time histories ([► Selection of Ground Motions for Response History Analysis](#), [► Time History Seismic Analysis](#)) to approximate the earthquake shaking at the site. The critical acceleration of a potential landslide can be determined in two ways: (1) For relatively simple slope models where material properties do not differ significantly between layers, Eq. 1 can be used to estimate the critical acceleration. (2) For more complex slope models that include layers having complex geometries or widely differing material properties, the critical acceleration should be determined using iterative pseudostatic

analysis, where different seismic coefficients are used until the static factor of safety reaches 1.0. The seismic coefficient yielding a factor of safety of 1.0 is the yield or critical acceleration.

Selecting an appropriate suite of strong-motion records ([► Selection of Ground Motions for Response History Analysis](#), [► Time History Seismic Analysis](#)) for the dynamic analysis can be challenging. Some key properties to consider in estimating ground motions and selecting records include earthquake magnitude, source distance, peak ground acceleration, Arias intensity, and shaking duration.

The significance of the Newmark displacements must be judged in terms of the probable effect on the potential landslide mass. For shallower landslides in brittle surficial rock and soil, estimated displacements in the 5–10-cm range commonly correlate with failure. For deeper landslides in more compliant material, estimated displacements in the 10–30-cm range more commonly correlate with landslide initiation. When displacements in this range occur, previously undisturbed materials can lose some of their strength and be in a residual-strength condition. Static factors of safety using residual shear strengths can then be calculated to determine the stability of the landslide after earthquake shaking (and consequent inertial landslide displacement) ceases.

Interpreting Minimum Ground Motions Required to Cause Slope Failure

If static stability analysis clearly indicates that failure of a landslide in aseismic conditions is highly unlikely, then an earthquake origin can be hypothesized. A dynamic analysis can then be used to estimate the minimum shaking necessary to have caused failure. Such an approach requires a general relationship between critical acceleration, shaking intensity (which can be characterized in various ways), and Newmark displacement. Several such relations have been published.

For example, consider a hypothetical landslide that is stable in aseismic conditions and that has a critical acceleration of 0.15 g . The following equation (Jibson 2007) could be used to estimate the minimum peak ground acceleration

(► **Selection of Ground Motions for Response History Analysis**) needed to cause failure:

$$\log D_N = 0.215 + \log \left[\left(1 - \frac{a_c}{a_{\max}} \right)^{2.341} \left(\frac{a_c}{a_{\max}} \right)^{-1.438} \right] \quad (2)$$

where D_N is Newmark displacement in centimeters, a_c is critical acceleration, and $a_{\max}$ is peak ground acceleration; the ratio of a_c to $a_{\max}$ is commonly referred to as the critical acceleration ratio. Applying this equation requires judgment regarding the critical amount of Newmark displacement that would reduce shear strength on the failure surface to residual levels and lead to continuing failure. The general guidelines stated previously suggest that a reasonable estimate of critical displacement might be 10 cm. For the hypothetical example under consideration, insertion of a displacement value (D_N) of 10 cm into Eq. 2 yields a critical acceleration ratio of 0.2. For a critical acceleration (a_c) of 0.15 g for the hypothetical landslide, this would yield a peak ground acceleration ($a_{\max}$) of 0.75 g as a minimum ground acceleration required to trigger enough displacement to cause general failure.

The peak ground acceleration from such an analysis could be used by itself as a basis for hazard assessment, or it could be used to estimate various magnitude/distance combinations of possible triggering earthquakes. If more than one landslide of identical age were similarly analyzed in an area, iterative magnitude and distance combinations could be optimized to estimate likely earthquake characteristics.

Equations that use other parameters are available and could be applied similarly. For example, a minimum threshold Arias (1970) intensity leading to slope failure can be estimated using the following equation (Jibson 2007) if a reasonable critical displacement can be specified:

$$\log D_N = 2.401 \log I_A - 3.481 \log a_c - 3.230 \quad (3)$$

where D_N is Newmark displacement in centimeters, I_A is Arias intensity in meters per second, and a_c is critical acceleration in terms of g.

Another approach for estimating ground motions from the results of slope-stability analyses uses a quantity referred to as $(A_c)_{10}$, which is the critical acceleration of a landslide that will yield 10 cm of displacement (the estimated critical displacement leading to catastrophic failure) in a given level of earthquake shaking. The following regression model relates Arias intensity to $(A_c)_{10}$:

$$\log (A_c)_{10} = 0.79 \log I_A - 1.095, \quad (4)$$

where $(A_c)_{10}$ is in g's and I_A is in meters per second (Crozier 1992). If the critical acceleration of a landslide can be determined, then this value can be used as the threshold value of $(A_c)_{10}$ in Eq. 4, and the Arias intensity that would trigger the critical displacement of 10 cm can be calculated.

Interpreting Results of Paleoseismic Landslide Studies

Once a landslide or group of landslides has been identified, dated, and linked to earthquake shaking, interpretations regarding the magnitude and location of the triggering earthquake can be made. The previous section outlined a method for detailed geotechnical analysis to address this issue, but in many cases such an analysis will be impossible owing to lack of data or the unsuitability of the landslide for detailed modeling. Several other approaches to this last level of paleoseismic interpretation are possible; in most cases, multiple lines of evidence will be required to make reasonable estimates of magnitude and location. Perhaps the most important aspect of such interpretation is a thorough understanding of the characteristics of landslides triggered by recent, well-documented earthquakes.

Characteristics of Landslides Triggered by Earthquakes

Comprehensive studies of landslides caused by historical earthquakes have allowed documentation of minimum earthquake magnitudes and intensities that have triggered landslides of

Paleoseismology and Landslides, Fig. 2 Dense concentration of disrupted slides and falls triggered by the 1994 Northridge, California, earthquake (M_w 6.7).

Virtually all of the *light-colored* areas in the photo are triggered landslides (Photograph by R.W. Jibson, U.S. Geological Survey)

various types, average and maximum areas affected by landslides as a function of magnitude, and maximum distances of landslides from earthquake sources as a function of magnitude (Keefer 1984, 2002). For these comparisons, landslides were grouped into three categories: disrupted slides and falls, including falls, slides, and avalanches in rock and soil (Fig. 2); coherent slides, including slumps and block slides in rock and soil and slow earth flows (Fig. 3); and lateral spreads and flows, including lateral spreads and rapid flows in soil and subaqueous landslides (Fig. 4).

Minimum Earthquake Magnitudes that Trigger Landslides

Table 2 shows the minimum magnitudes of earthquakes that have triggered various types of landslides. Landslides of various types have threshold magnitudes ranging from 4.0 to 6.5; the more disrupted types of landslides have lower threshold magnitudes than the more coherent types of slides. Although smaller earthquakes could conceivably trigger landslides, such triggering by

very weak shaking probably would occur on slopes where failure was imminent before the earthquake.

Minimum Shaking Intensities that Trigger Landslides

Table 3 shows the lowest Modified Mercalli Intensity (MMI) values and the predominant minimum MMI values reported where the three categories of landslides occurred. The data show that landslides of various types are triggered one to five levels lower than indicated in the current language of the MMI scale.

Areas Affected by Earthquake-Triggered Landslides

Drawing boundaries around all reported landslide locations in historical earthquakes and calculating the areas enclosed yields a plot of area versus earthquake magnitude (Fig. 5); a well-defined upper bound curve represents the maximum area that can be affected for a given magnitude (Keefer 1984). Average area affected by landslides as a function of earthquake magnitude

Paleoseismology and Landslides, Fig. 3 Rotational slump that moved as a coherent landslide in the 2004 Niigata Ken Chuetsu, Japan, earthquake (M_w 6.8) (Photograph by D.S. Kieffer, Graz University of Technology, Austria)

Paleoseismology and Landslides, Fig. 4 Lateral-spread landslide triggered by the 1980 Mammoth Lakes, California, earthquake (M_w 6.2) (Photograph by E.L. Harp, U.S. Geological Survey)

can be predicted using the following regression equation (Keefer and Wilson 1989):

$$\log A = M - 3.46 \pm 0.47 \tag{5}$$

where *A* is area affected by landslides in square kilometers and *M* is a composite magnitude term, which generally indicates surface-wave

Paleoseismology and Landslides, Table 2 Minimum earthquake magnitude required to trigger landslides

Earthquake magnitude	Type of landslide
4.0	Rock falls, rock slides, soil falls, disrupted soil slides
4.5	Soil slumps, soil block slides
5.0	Rock slumps, rock block slides, slow earth flows, soil lateral spreads, rapid soil flows, subaqueous landslides
6.0	Rock avalanches
6.5	Soil avalanches

Note: Data from Keefer (1984)

Paleoseismology and Landslides, Table 3 Minimum modified Mercalli intensity required to trigger landslides

Landslide type	Lowest modified Mercalli intensity	Predominant modified Mercalli intensity
Disrupted slides and falls	IV	VI
Coherent slides	V	VII
Lateral spreads and flows	V	VII

Note: Data from Keefer (1984)

Paleoseismology and Landslides, Fig. 5 Area affected by seismically triggered landslides plotted as a function of earthquake magnitude. *Solid line* is upper bound of Keefer (1984); *dashed line* is from Rodriguez et al. (1999); *dotted line* is regression line from Keefer and Wilson (1989)

magnitudes below 7.5 and moment magnitudes above 7.5. Area affected by landslides also is influenced by the geologic conditions that control the distribution of susceptible slopes and by the focal depth of the earthquake.

Maximum Distance of Landslides from Earthquake Sources

The maximum distance of the three categories of landslides from the earthquake epicenter and from the closest point on the fault-rupture surface relates closely to earthquake magnitude (Fig. 6). Upper bound curves are well defined and are constrained to pass through the minimum threshold magnitudes shown in Table 2 as distance approaches zero. Although the upper bounds shown have been exceeded a few times in subsequent earthquakes, they remain fairly reliable indicators of the maximum possible distances at which the three classes of landslides could be triggered in earthquakes of various magnitudes.

Figure 6 indicates that disrupted slides and falls have the lowest shaking threshold and that lateral spreads and flows have the highest shaking threshold. As with area, earthquakes having focal depths greater than 30 km generally triggered landslides at greater distances than shallower earthquakes of similar magnitude.

Interpreting Earthquake Magnitude and Location

Figures 5 and 6 and Tables 2 and 3 allow interpretation of earthquake magnitude and location in

Paleoseismology and Landslides, Fig. 6 Maximum distance to landslides from (a) epicenter and (b) fault-rupture zone for earthquakes of different magnitudes. *Dashed line* is upper bound for disrupted slides and falls;

dash-double-dot line is upper bound for coherent slides; and *dotted line* is upper bound for lateral spreads and flows (Modified from Keefer 1984)

a variety of ways. If a single landslide is identified as being seismically triggered, then a minimum magnitude and MMI can be estimated based on the landslide type. If several landslides in an area are identified as being seismically induced, then application of the magnitude-area and magnitude-distance relationships can yield minimum magnitude estimates. As the area in which landslides documented to have been triggered by the same earthquake increases, the estimated magnitude will increase toward the actual magnitude of the triggering earthquake. Therefore, documentation and analysis of landslides over a large area will produce more accurate magnitude estimates. If seismic source zones are well documented, then the distance from the closest source zone to the farthest landslide will yield a reasonable minimum magnitude estimate. The observation that greater source depth relates to greater areas affected and greater source distances for landslides of all types further complicates estimation of earthquake magnitude.

For a specific region, earthquake magnitude can be estimated based on comparison of

paleoseismic landslide distribution with landslide distributions from recent, well-documented earthquakes in the region.

Earthquake locations generally are estimated based on the distribution of synchronous landslides attributed to a single seismic event. In a broad area of roughly similar susceptibility to landsliding, the earthquake epicenter probably will coincide fairly closely with the centroid of the landslide distribution. In areas of highly variable or asymmetrical landslide susceptibility, epicentral estimation is much more difficult and subject to error. In areas where seismic source zones are well defined, the epicentral location is best defined as the point in a known seismic source zone (or along a known seismogenic fault) closest to the centroid of the landslide distribution.

Additional Considerations

The primary limitation of paleoseismic analysis of landslides is the inherent uncertainty in

interpreting a seismic origin. Unlike liquefaction, which can occur aseismically only in relatively rare conditions, landslides of all types form readily in the absence of earthquake shaking as a result of many different triggering mechanisms. In many cases, ruling out aseismic triggering will be impossible, and the level of confidence in any resulting paleoseismic interpretation will be limited. For this reason, paleoseismic landslide analysis should include, so far as possible, multiple lines of evidence to constrain a seismic origin. In this way, a strong case can be built for seismic triggering of one or more landslides, even if no single line of evidence is unequivocal. Where independent paleoseismic evidence from fault or liquefaction studies is available, paleoseismic landslide evidence can provide useful corroboration.

Detailed slope-stability analyses generally can be performed only on certain types of landslides. Failure conditions of falls, avalanches, and disrupted slides cannot easily be modeled using Newmark's method, and even static stability analyses of these types of slides can be very problematic. Also, the pre-landslide geometry of slides in very steep terrain can be difficult or impossible to reconstruct. Thus, detailed dynamic slope-stability analysis can be applied only to fairly coherent landslides where pre-landslide geometry can be reconstructed with confidence, where groundwater conditions can be modeled reasonably, and where the geotechnical properties of the materials can be accurately measured.

Even allowing for these limitations, paleoseismic landslide studies have been extremely useful where applied successfully, and they hold great potential in the field of paleoseismology. Dating landslide deposits is, in many cases, easier than dating movement along faults because many different dating methods can be used on the same slide to produce redundant results. In addition, landslides have the potential for preserving large amounts of datable material in the various parts of the slide (scarp, body, toe, etc.). In areas containing multiple or poorly defined seismic sources, paleoseismic ground-failure analysis might be preferable to

fault studies because landslides preserve a record of the shaking history of a site or region from all seismic sources. Knowing the frequency of strong shaking events could, in many cases, be more critical than knowing the behavior of any individual fault.

Paleoseismic landslide analysis could have greatest utility in assessing earthquake hazards in stable continental interiors where fault exposures are rare or absent but where earthquakes are known to have occurred. In such areas, analysis of earthquake-triggered ground failure, both landslides and liquefaction, might be one of the few paleoseismic tools available.

Another advantage of paleoseismic landslide analysis is that it gets directly at the effects of the earthquakes being studied. Ultimately, most paleoseismic studies are aimed at assessing earthquake hazards. Fault studies can be used to estimate slip rates, recurrence intervals, and, indirectly, magnitudes. From these findings, the effects of a possible earthquake on such a fault are extrapolated. In paleoseismic landslide studies, the effects are observed directly. Thus, if a seismic origin can be established, a landslide shows directly the effects of some previous earthquake. Even if magnitude and location are poorly constrained, at least a partial picture of the actual effects of seismic shaking in a locale or region can be estimated.

In conclusion, paleoseismic landslide analysis can be applied in a variety of ways and can yield many different types of results. Although interpretations are limited by the certainty with which a seismic origin can be established, paleoseismic landslide studies can play a vital role in the paleoseismic interpretation of many areas, particularly those lacking fault exposures.

Summary

In many environments, landslides preserved in the geologic record can be analyzed to determine the likelihood of seismic triggering. If evidence indicates that a seismic origin is likely for a landslide or group of landslides, and if the landslides can be dated, then a paleoearthquake

can be inferred, and some of its characteristics can be estimated. Such paleoseismic landslide studies thus can help reconstruct the seismic shaking history of a site or region. In regions that contain multiple seismic sources and in regions where surface faulting is absent, paleoseismic ground-failure studies are valuable tools in hazard and risk studies that are more concerned with shaking hazards than with interpretation of the movement histories of individual faults. Paleoseismic landslide analysis involves three steps: (1) identifying a feature as a landslide, (2) dating the landslide, and (3) showing that the landslide was triggered by earthquake shaking. Showing that a landslide was triggered by seismic shaking can be challenging, but some types of landslides can be analyzed using established static and dynamic methods of slope-stability analysis to determine the likelihood of seismic triggering and to estimate minimum shaking levels required to initiate landslide movement.

Introduction

Important earthquakes are often accompanied by vertical-land displacements. Therefore in coastal

areas they may result in rapid changes of the relative sea level. An essential tool for the study of coastal paleoseismicity is the identification of fossil paleoshorelines, paying special attention to sea-level indicators that are consistent or provide evidence of rapid relative sea-level change.

Here, different types of sea-level indicators that are often used in literature in order to determine changes in fossil shorelines are summarized. Information is also provided regarding four case studies of important earthquakes that occurred in Greece (in AD 365, 1953, and 1956) and in Japan (in 1923).

How Can Fossil Paleoshorelines Be Identified?

Fossil paleoshorelines can be identified and traced from geomorphological, biological, sedimentological, stratigraphical, or archeological sea-level indicators.

The coastal geomorphological features that are used as sea-level indicators are the result of either erosional or depositional processes. Erosional features can only be preserved on hard, solid rocks, and in some cases they constitute indicators of sea-level change. Such indicators are marine notches, potholes, abrasion platforms, etc. Among the depositional formations, marine terraces and beachrocks stand out as the most important sea-level indicators.

Erosional Geomorphological Sea-Level Indicators

Tidal notches are well known as precise sea-level indicators that usually undercut limestone cliffs in the midlittoral zone (e.g., Pirazzoli 1986), which renders them the most important erosional geomorphological sea-level indicators. In microtidal areas sheltered from wave action, elevated or submerged notches are used to indicate former sea-level positions, with up to a decimeter confidence.

Bioerosion by endolithic organisms and surface feeders grazing upon epi- and endolithic algae are generally acknowledged to play an important role in tidal-notch development.

The erosion rate is generally highest near mean sea level (MSL) and decreases gradually toward the upper and lower limits of the intertidal range. Accordingly, in places sheltered from continuous wave action, if MSL remains stable, notch profiles will be typically reclined U shaped or V shaped, with a vertex located near MSL, the base of the notch near the lowest-tide, and the top near the highest-tide level. In a moderately exposed site, continuous wave action may splash seawater onto the roof, thus shifting the top of the notch upward, above the highest-tide level.

The rate of maximum undercutting (near MSL) varies with the rock type and the local climate and has been roughly estimated to be of the order of 1 mm/year (Laborel et al. 1999). However this is only a first-order value, while lower rates are generally observed in hard limestones, especially in nontropical areas. More detailed estimations show a range varying from 0.2 to 5 mm/year, depending on lithology, location, and probably duration of bioerosion (for references, see Pirazzoli 1986, Table 1 and Laborel et al. 1999, Table 1).

When a tidal notch is uplifted or submerged, its profile may provide valuable information concerning the type of the paleoseismic event, e.g., whether one or more events took place, whether the movement was coseismic or gradual, etc.

Depositional Geomorphological Sea-Level Indicators

Marine Terraces

Marine terraces are quite common coastal features, owing their presence to a combination of eustatic and crustal processes (Pirazzoli 1994).

The presence of a sequence of uplifted, stepped marine terraces usually corresponds to the superimposition of eustatic change in sea level and of a tectonic uplifting trend that may include sequences of paleoseismic events. The presence of marine terraces several hundred meters above sea level indicates tectonic uplift and allows the estimation of the long-term rate of tectonic deformation.

Marine terraces' age usually increases with altitude, while conservation quality decreases. When uplifted marine terraces are used for the study of sea-level changes, the uplift rate of each section is considered to have remained constant and the eustatic sea-level position corresponding to at least one uplifted terrace has to be known. Marine terraces usually provide evidence of tectonic trends rather than of single paleoseismic events.

Terms often used by geomorphologists for marine terraces are the "beach angle" or "shoreline angle," expected to indicate a frequent sea-level (and wave) position during the period of terrace formation. However, in some cases it can be difficult to precisely determine shoreline angles for Pleistocene marine terraces, during which relative sea-level changes are not known in great detail. This approach can be more useful for Holocene marine terraces and beach ridges formed between two successive coseismic uplifts, like near the Wairarapa Fault in New Zealand where the mean earthquake recurrence time is expected to be of $1,230 \pm 190$ years (Little et al. 2009).

Beachrocks

Beachrock formation is a diachronic and wide-ranging sedimentary process, and since lithification takes place at the coastline, beachrocks have been used as indicators in Quaternary sea-level and neotectonic studies (e.g., Kelletat 2006).

There are, however, several problems in the use of beachrocks as sea-level indicators; the most important are mentioned next. It is difficult to determine the upper level of beachrock cementation, which may correspond to the mean high water springs, and in regions with high tidal range, this limit may be quite large. Another insurmountable problem arises from fluctuations in the tidal range, originating from local changes in the coastal configuration.

Within a sedimentary body, the cementation zone rises and falls following the perpetual tidal cycle of sea-level rise and fall; thus the lower level of cementation zone will correspond to the lowest sea level, at any time during this sedimentary body's existence. Therefore, the cementation

of the lower level of an exposed formation may have occurred at an earlier stage, during a rising sea level, more recently during a falling sea level, or during any variation. Consequently, only the upper limit of beachrocks constitutes an accurate indicator of past tidal level.

Additionally, there is the possibility of confusion with other cemented materials in the intertidal zone, although a careful study of the cement, the composition, and the microstructure of the sample can accurately determine the type of formation.

Submerged beachrocks or raised deposits may give evidence of tectonic activity in the area, but it is not possible to provide information on whether this displacement is based on one or more paleoseismic events and whether this movement was rapid or slow.

Biological Sea-Level Indicators

The biological zonation depends essentially on wave exposure. One may distinguish a supralittoral zone, a midlittoral zone, and an infralittoral zone.

The biomass of the supralittoral zone is very low (presence of lichens such as *Verrucaria* or *Lichina* and/or of associated endolithic *Cyanobacteria*) and bioconstruction is uncommon but may occur in the form of incrustations by *Chthamalus* shells in shaded rock crevices exposed to wave splash. Limited erosion may take place, mainly due to boring activity in carbonate substrate. According to Le Campion-Alsumard (1979), endolithic microorganisms may create many microtunnels, with their roots, that are easily preserved and fossilized; these marks may be suitable as paleobathymetric indicators. Other algae, which may occur in the lower supralittoral zone, are the green *Endoderma* and the brown *Chrysophyceae*, which may be outgrown by various other algae. The most widespread animals in the lower supralittoral zone are the gastropods *Littorina* and *Melanerita*, which graze the algae, some crustaceans, and occasionally opportunistic visitors that do not normally reside there, such as hermit crabs, insects, spiders, birds, and small rodents (Pirazzoli 1996).

The midlittoral zone is submerged at close intervals by waves and tide. The upper part of this zone is never rich in species and even barren for most of the year on the Arctic and Antarctic shores, due to the grinding action of ice and may become vegetated by benthic diatoms and ephemeral algae only during the summer. *Fucus* and *Pelvetia* algae are frequent in North Atlantic and North Pacific coasts. Farther south a greater amount of annual species is found, and the importance of *Cyanobacteria* increases at the tropics. Lithothamnium species have been observed on exposed shores of the Indian and Pacific Ocean, as well as *Cladophora*, *Ectocarpus*, and *Ulva*. The lower part of the midlittoral zone is in general densely covered by furoid and turf algae, which are grazed by several herbivores (littorinoids, limpets).

Barnacles (*Balanus*, *Elminius*, *Tetraclita*, and especially *Chthamalus*) live in the upper part of the midlittoral zone, while mussels (*Mytilus*) and oysters tend to occupy lower levels. Barnacles, mussels, oysters, and *Lithophyllum* form a rim just above sea level in the western Mediterranean and may be fossilized in situ after death.

Erosive agents include many *Cyanobacteria* in the upper part of this zone and limpets (*Patella*) and Chitons in the lower part.

The infralittoral (or sublittoral) zone extends from the biological mean sea level (BMSL) (Laborel and Laborel-Deguen 1994), located at the base of the midlittoral zone, to a depth of 25–50 m (depending on water transparency) but may be absent in very turbid coastal waters. The position of the BMSL in relation to the tide-gauge MSL varies with exposure.

This zone is densely populated by brown algae, coralline encrusting algae (*Porolithon*, *Neogoniolithon*, *Lithophyllum*), fixed vermetid gastropods (e.g., *Dendropoma*, *Vermetus*, *Serpulorbis*), cirripedes like *Balanus*, or coral reefs in warm waters. They may be accompanied by turf-forming algae and furoid vegetation (*Fucus*, *Cystoseira*, *Sargassum*) that are grazed by herbivorous fish and sea urchins; the latter like clionid sponges and other borers (e.g., *Lithophaga*) may also attack the rocky substrate.

All bioconstructions (encrusting algae, vermetids, reef-building corals and associates, barnacles, and oysters) may fossilize in situ in the sublittoral zone. The most accurate altimetric indications for the estimation of past sea levels derive from the comparison of the fossil bioconstructions with their present-day counterpart. The most useful sea-level indicators are those with the narrowest vertical zonation, e.g., the upper level of coral microatolls and rims made by *Dendropoma* or *Neogoniolithon*. Fossil *Lithophaga*, which are frequently used to indicate uplift on carbonate shores, deserve special mention. They are generally a poor sea-level indicator, because they live between the upper limit of the sublittoral zone and depths greater than 30 m. However, when the upper limit of their population is well marked and forms a horizontal line, it corresponds to the BMSL. Nonetheless, as reported by Shaw et al. (2010), *Lithophaga* shells tend to incorporate host-rock carbon, thus giving older apparent radiocarbon ages. More details on the vertical range, altitudinal accuracy, and resistance to erosion of various Mediterranean midlittoral and infralittoral sea-level indicators are given by Laborel and Laborel-Deguen (1994).

Although biological indicators are very useful for dating an uplift, they are unlikely to be preserved when they are submerged because of the subsequent bioerosion. An additional indicator is useful for diagnosing the type of the paleoseismic event, e.g., coseismic or gradual. In any case, if the shoreline has quickly shifted from the tidal zone, the biota will be well preserved, while slow emergence will expose it leading to gradual destruction in the supralittoral wave zone.

Sedimentological/Stratigraphical Sea-Level Indicators

The most common method for locating material that will provide information regarding sea-level change is the use of a vibrating sampler, provided that samples are slightly moderately disturbed. The method of excavation trenches is also often used for smaller depths.

In order to acquire accurate results from coring, it is necessary to obtain a solid and undisturbed sample, so that the conditions are similar to the ones prevailing at the sampling location. There are several biomarkers, present in sampling cores, which can be dated and associated to paleo-sea levels. An indispensable requirement is the recording of the precise location and height of the sampling with differential GPS.

A stratigraphic column may provide evidence of the paleogeographic/paleoenvironmental changes that originated from paleoseismic events, while it may provide clear evidence of paleo-tsunami in the area. In a stratigraphic column history is fossilized making clear whether transition was slow or abrupt. If datable material is available, the event could be dated as well.

Archeological Sea-Level Indicators

Most archeological remains provide no evidence on how far from sea level they were constructed. A human civilization may not be linked to the sea, and in most cases it is impossible to distinguish a house or pottery found near the sea from an equivalent found some kilometers inland. On the other hand, the civilization may have developed specific activities, closely related to the sea, requiring sailors, fishermen, boat builders, and salt gatherers. In this case the settlement was probably built close to the shore.

Apart from the undisputable evidence of minimum relative sea-level rise, provided by submerged structures that had to have their foundations on dry land (houses, tombs, mosaic floors, passageways, storage tanks, tells, middens), many archeological findings refer to structures that were partly in the sea and may be considered as reliable sea-level indicators (slipways, breakwaters, jetties, quays, docks, channels, drains, salt pans, the lowest part of certain flights of steps or of coastal quarries that used a wood splitting wedge for cutting the lowest level of stones, or finally installations for fishing or fish farming). For a reliable estimation of the ancient sea level, a good understanding of the functionality of the structure and the local

hydrographic and climatic constraints is always essential.

In any case the ruins may provide valuable information concerning the paleoseismic events in an area. For example, around 3300 BP an earthquake destroyed House B in Grotta (Naxos Island, Cyclades). The archeologists who excavated Grotta and Aplomata on Naxos spoke of two seismic events: one at an early phase of the LH IIIA2 and another one in LH IIIC period, based on the ruins of the archeological sites. The destruction of the site known as "Kolona," literally "Column," at Heraion (Samos Island, Eastern Aegean), has been assigned to seismic damage. The drums of the only surviving column are offset laterally and tilted. This effect was clearly the result of rocking produced by a strong earthquake. The coeval destruction of at least one other temple nearby supports the possibility of a destructive earthquake circa 530 BC.

Structures Partly in the Sea

Most known examples (e.g., Flemming 1979) come from the tideless Mediterranean, where much well-preserved material exists. However, similar methods and techniques have also been occasionally adopted in fully tidal waters.

Gradients for ancient slipways may vary from 4° to 15°, and the original position of the sea level can be calculated approximately by making assumptions about the water depth needed at the foot of the structure to take the bow of the boat and the length of slipway needed to be dry to support the boat while work was done on it. Well-preserved slipways in the Mediterranean can provide an accuracy of sea-level estimate of ± 0.25 m.

Breakwaters, jetties, and moles are generally walls, built to create a barrier between the open sea and a calm sheltered area of water, where ships may safely moor. Mooring quays are built on the inner side. The base of the breakwater was in the water, while the top must have been out of the water, high enough to prevent waves from climbing over. Protection moles have often been constructed around Roman fish tanks. Since the upper part of the majority of these structures has

been damaged by countless storms, the identification of the upper level is generally problematic. However, when the upper surface is intact, the ancient sea level may be estimated within ± 1 m.

Quays are well-squared structures built to provide mooring for ships, access for men, and storage space for cargoes. They were often associated with steps leading down to the vessels, mooring stones, bollards, and warehouses. Quay surfaces varied generally around 1.0–2.0 m. Through the combination of the water depth at the foot of the quay wall, the level of the mooring stones, surfaces reached by steps, and the main working surfaces of the quay, it may be possible, according to Flemming (1979), to determine the original sea level to about ± 0.5 m.

Docks are small rectangular basins in which a ship can be berthed and the basin can be pumped dry. The interpretation of docks is similar to that for quays.

Fish Tanks

Though stone fish traps and turtle pens have been reported in many cultures (e.g., Caribbean Indian and Australia aborigine), Roman fish tanks (*piscinae*) are worth special mention. Such installations were especially frequent along the Tyrrhenian coasts of central Italy between the first century BC and the first century AD, when they came into fashion for wealthy Romans. When certain elements are well preserved and the functioning of the structure is well understood, fish tank remains allow estimating with excellent accuracy (± 0.1 m) the sea-level position of about 2,000 year ago. The main sea-level indicators are the top of closing gates (*cataractae*), generally slightly above the high-tide level. In several examples they were located near the top of the walls (*crepidines*) delimiting the basins from where they could be easily worked, by using the *crepidines* as a footwalk. For several other coastal structures, like salt pans, foundations of towers and lighthouses, roads, seaside villas, wells, etc., the exact relation to the sea level may vary between sites.

How Can Fossil Paleoshorelines Be Dated? Radiocarbon, Archeological Remains, Coastal Cores, and Historical Information

Fossil paleoshorelines can be dated through sea-level indicators, using different methods, depending on the type of indicators available. For example, radiocarbon dating of biological indicators is one of the easiest and most trustworthy methods. On the other hand, this is not possible with submerged paleoshorelines since any biological indicator is destroyed by bioerosion occurring after submergence. In this case other, indirect ways of dating fossil paleoshorelines are used. In some cases it is possible to date a relative sea-level change, based on an ancient site in the nearby area.

Emerged or submerged beachrocks may be dated, but their accurate dating is a very difficult task, even though biogenic materials such as shells or corals can easily be dated by radiocarbon. The age acquired corresponds to the time of the organism's death. After death, the organism was transported and deposited on a beach and later was cemented into the beachrock. Although in many cases this sequence may be complete within a few years, it is likely that the time interval between the death of the organism and the cementation of the beachrock may last hundreds or thousands of years. For this reason, the age acquired by dating a constituent organism may be regarded as a maximum for the cementation of beachrock. The minimum age for this process is only attainable by dating the cement. However, several difficulties may arise with extracting the adequate amount of cement, especially in submerged beachrocks. Furthermore, it is possible that after exposure, water passing through beachrock may cause carbonate exchange resulting in continuous renewal of the apparent cementing age.

Dating material provided by coastal cores could often be the only solution, especially in cases where biological, geomorphological, and archeological sea-level indicators are absent from a study area, or their dating is impossible. In relatively recent sediments, which were

deposited in various geoenvironments, a variety of information that determines the paleogeography of a region and the various changes in sea level is recorded, through datable material found at a certain depth of the stratigraphic column. In these cases, depth precision is determined by the accuracy of the relationship of the biological marker to mean sea level. However, an uncertainty is added in all estimations, especially if the cores come from marsh deposits where compaction can be significant and the positional uncertainty of the biological markers increases considerably.

How Can Coseismic Sea-Level Changes Be Distinguished from Gradual Changes?

The best indicators to distinguish rapid relative sea-level changes from gradual ones are tidal notches. The shape of the notch profiles may provide qualitative information on the rate of sea-level change and on tectonic movements. In the case of a rapid (e.g., coseismic) emergence greater than the tidal range, the notch that is completely emerged will be preserved from further marine bioerosion, while a new notch will develop in the new lower intertidal zone (Pirazzoli 1986). On the other hand, in the case of rapid submergence greater than the tidal range, the whole notch will be submerged. It will not be completely preserved, due to further bioerosion as in the case of emergence, and its profile will be uniformly deepened by the rate of bioerosion that predominates in the infralittoral zone, while a new tidal notch will develop in the intertidal range. However, the infralittoral bioerosion rate is generally estimated to be one order of magnitude less than the intertidal one.

If the rapid submergence is smaller than the tidal range, the height of the notch will increase, with further deepening in the new intertidal zone, while the part of the notch below the low tide level will continue to deepen at a much slower rate, and the notch profile will be marked by an undulation at the level of the roof of the former notch. Finally, in the case of gradual

Paleoseismology of Rocky Coasts, Fig. 1 Different profiles of notches that give evidence of a rapid movement caused by earthquakes with magnitude larger than 6.0 Mw, commonly associated to morphogenic faults producing direct surface faulting (Ambraseys and Jackson 1990) and ground deformation (Pavlidis and Caputo 2004)

submergence, the height of the notch will gradually increase, the lower part of its profile becoming higher than the upper part, and no marked undulation will appear in the profile. Many combinations of vertical movements leading to emergence or submergence are possible, as well as different erosion rates, tidal ranges, and periods of time, but even so, notch profiles would be similar to those of Fig. 1.

Case Studies

AD 365, Crete Earthquake

On 21 July AD 365, a strong underwater earthquake occurred near the southwestern part of Crete. Nearly all towns in the island were

Paleoseismology of Rocky Coasts, Fig. 2 Remains of at least three fossil ripple notches have been preserved between +4.00 and +4.75 m below Afrata (1.5 km N of Gonias, near the eastern foot of Rodopos peninsula).

These tidal notches have probably developed a few centuries before the general uplift of AD 365 (Photo P.A.P. n° 3904, Sept. 1977)

destroyed, and widespread damage extended to central and southern Greece, northern Libya, Egypt, Cyprus, and Sicily. The earthquake was followed by a tsunami that devastated the southern and eastern coasts of the Mediterranean, particularly Libya, Alexandria, and the Nile Delta, hurling ships nearly two miles inland. The Roman historian Ammianus Marcellinus described in detail the tsunami hitting Alexandria.

In Crete, systematic geomorphological surveys carried out in the late 1970s (Pirazzoli et al. 1982) showed that a block of lithosphere approximately 200 km long, extending from central Crete to the small Antikythera island, was uplifted and inclined northeastward. The uplift reached a maximum of 9 m in southwestern Crete, leaving along the coast a very visible emerged shoreline that has been dated by radiocarbon in many positions and also remains of Roman harbors, like in Kisamos and Falasarna (where the coseismic uplift reached about 6 m).

If the AD 365 tsunami is well dated historically, direct historical evidence confirming that such uplift in Crete was synchronous to the earthquake that produced the tsunami is generally missing, and many radiocarbon dates converge

only by a few decades toward the critical period. A closer connection to a major destructive earthquake that occurred shortly after AD 355/361 in Crete was established archeologically by a number of coins found in Kisamos among skeletons of people killed and buried by fallen debris (Stiros and Papageorgiou 2001).

If the type and geometry of the fault, which produced the block movement, are still a matter of debate, some geomorphological elements provide information on the preparatory phase that permitted the necessary strain accumulation of the major earthquake. These elements consist of nine fossil shorelines, preserved as ripple notches in Antikythera and as bioconstructed vermetid rims at Moni Khrisoskalitisas, remnants of which have been reported in several sites (e.g., Plaka, Falasarna, Koutsounari, Afrata, Damnoni, Sougia) (Fig. 2) showing that the western part of the block uplifted in AD 365 underwent between 4,000 and 1,700 year BP, along a length of at least 150 km, ten small coseismic subsidences (from 10 to 25 cm each time), apparently due to gravitational forces, without any noticeable tilting (Pirazzoli et al. 1981, 1982). Shaw et al. (2010) attempted to narrow the chronology of the subsidence movement having preceded the AD

Paleoseismology of Rocky Coasts,

Fig. 3 Submerged fossil shoreline in Keros island, which has been also located along the rocky coasts of Sifnos, Antiparos, Paros, Naxos, and Iraklia, reveals a widespread evidence of a recent subsidence, part of which according to Evelpidou et al. (2012b) is due to Amorgos 1956 earthquake

365 uplift event by using *Lithophaga* shells and showing that these shells may incorporate host-rock carbon. If the reality of such incorporation by *Lithophaga* shells has been confirmed by Evelpidou et al. (2012a) for tsunami deposits in the Gulf of Euboea, however the chronological narrowing proposed by Shaw et al. (2010) cannot be applied to Crete before AD 365, because the time of the subsidence events dated by Pirazzoli et al. (1981, 1982) were not deduced from lithophagid dates, but from organic accretions of *Dendropoma*, *Neogoniolithon*, *Lithophyllum*, other calcareous algae, and *vermetids*, which are excellent sea-level indicators providing reliable radiocarbon-age estimations.

1956, Cyclades: Amorgos Earthquake

The Amorgos earthquake, on 9 July 1956 in the south central Aegean Sea, was one of the largest ($M_S = 7.4$) and most destructive crustal earthquakes in the twentieth century in the Aegean and was followed by a more destructive aftershock ($M_S = 7.2$) (Makropoulos et al. 1989).

The whole event resulted in 53 deaths and considerable damage notably on the island of Santorini and generated a local tsunami, which

affected the shores of the Cyclades and Dodecanese Islands, Crete, and the coast of Asia Minor, with run-up values of 30, 20, and 10 m reported on the southern coast of Amorgos, Astypalaia, and Folegandros, respectively (Papastamatiou et al. 1956; Galanopoulos 1960; Soloviev et al. 2000).

According to Evelpidou et al. (2012b), an extended underwater geomorphological survey located a well-developed submerged notch along the rocky coasts of Sifnos, Antiparos, Paros, Naxos, Iraklia, and Keros (Fig. 3), revealing widespread evidence of a recent 30–40 cm submergence, part of which may have seismic origin.

Comparison with information reported from earthquakes having affected the area suggests that at least part of the recent submergence might be an effect of the 1956 Amorgos earthquake. Modeling of the coseismic and short-term postseismic effects of the earthquake revealed that part of the observed subsidence may be explained in some of the islands by a fast postseismic relaxation of a low-viscosity layer underlying the seismogenic zone. However far-field observations are underestimated by

Evlepidou et al. (2012b) model and may be affected by a wider deformation field induced by the largest aftershock of the Amorgos sequence or by other earthquakes.

1953, Ionian: Cephalonia Earthquake

The region of Cephalonia and Ithaca islands is characterized by the frequent occurrence of shallow seismic events with magnitudes up to 7.2. Based on historical documents, large earthquake events took place in 1469, 1636, 1767, 1867, and 1953, while moderate-to-large ones occurred in 1658, 1723, 1742, 1759, 1766, 1862, 1912, 1915, 1925, 1932, and 1939 (Papagiannopoulos et al. 2012). The most destructive earthquake in the region hit the area in 1953. The 1953 series of earthquakes greatly damaged or destroyed 91 % and 70 % of all houses in Cephalonia and Ithaca, respectively. The first earthquake of the series occurred on 9 August and hit Ithaca and the town of Sami (Cephalonia). The second one occurred on 11 August and was greater than the first, destroying many towns around Cephalonia: Argostoli, Lixouri, Agia Efimia, and Valsamata. The third one on 12 August had a magnitude of 7.2 and completely destroyed Cephalonia, Ithaca, and Zakynthos. The number of human casualties as well as curves that illustrate the distribution of

seismic intensity has been given by Grandazzi (1954).

According to the map of seismic intensity by Grandazzi (1954, Fig. 3), in Cephalonia a seismic intensity of IX is observed for most part of the island, with the exception of Fiscardo peninsula, where the intensity was VII. In addition, in Ithaca island an intensity of IX was measured for the southern part, while in the northern one the intensity was smaller (VIII). This is also illustrated on the map of destruction by Grandazzi (1954, Fig. 4) (Poros, Cephalonia), where the percentage of destructions both in Ithaca and Cephalonia are increased toward the south.

The observations of Galanopoulos (1955) and Mueller-Miny (1957) about the uplift of the shorelines of Cephalonia during 12 August 1953 earthquake were also verified by Stiros et al. (1994). In fact, the 1953 earthquake left recognizable uplifted marks in several places around Cephalonia island, which reach a maximum elevation of +0.7 m in Poros area (Fig. 3). In fact, the uplift is ranging from 30 to 70 cm and has been evident in the central part of the island. According to Stiros et al. (1994), the uplifted part is bounded by two subparallel and homothetic major thrusts and can be better explained if assumed that the surface deformation reflects a

Paleoseismology of Rocky Coasts,

Fig. 4 Holes made by *Lithophaga* shells in a tufa layer of Miura Peninsula uplifted by the 1923 earthquake (Photo P.A.P. n° 595, 1974)

Paleoseismology of Rocky Coasts, Fig. 5 Uplifted fossil shorelines in Poros area (Cephalonia). The lower one at +0.7 m is ascribed to the 1953 earthquake

halotectonic deformation, indicating that the seismic deformation of the uppermost crustal strata in the area may mimic the style of the long-term halotectonic deformation.

The study of Stiros et al. (1994) shows that no postseismic displacement occurred after the 1953 coseismic uplift (Fig. 4) (Poros, Cephalonia).

1923, The Great Japan Earthquake

On 1 September 1923, shortly before noon (at 2 h 58' 44" GMT), a violent shock of earthquake occurred, shaking houses and other buildings intensely. A second and a third quake followed shortly after and then many aftershocks, spreading disaster all over. The afflicted zone covered seven prefectures: Tokyo, Kanagawa, Shizuoka, Chiba, Saitama, Yamanashi, and Ibaraki. The fire that followed reduced to ashes a great part of Tokyo and of the port of Yokohama.

According to the Bureau of Social Affairs (1926), the number of houses having been

damaged in Tokyo and Kanagawa Prefectures is of:

- 381.090 (54.9 %) entirely burnt
- 517 (0.1 %) partially burnt
- 83.319 (12.1 %) entirely collapsed
- 91.233 (13.1 %) partially collapsed
- 1.390 (0.2 %) swept away
- 136.572 (19.6 %) damaged

This makes a total of 558.049 (80.4 %) houses entirely or partially burnt, entirely or partially collapsed, or swept away due to the earthquake or the fire that followed.

According to <http://earthquake.usgs.gov/learn.today/index.php?r>, the magnitude M_L of this earthquake was 8.3 and it produced a death toll of 142,800.

The uplift of the ground in the disturbed zone was generally (Fig. 4) (Miura Peninsula) along 15 km of coast, especially in Tokyo Bay and Sagami Bay, reaching a maximum of 1.8 m in

Paleoseismology of Rocky Coasts, Fig. 6 Abrasion coastal platform uplifted in 1923 at Miura Peninsula. Water level (at Aburatsubo tidal station) is at -76 cm. Spring tidal amplitude is ± 54 cm (Photo P.A.P. 592, May 1974)

Chiba Prefecture, while more to the south (e.g., Oshima (Vries Island)) the ground sunk (Fig. 6).

Summary

Paleo-sea levels estimated through indicators such as geomorphological, biological, sedimentological, stratigraphical, or archeological may give evidence of coastal paleoseismicity. After the indicators' identification comes the important step of interpretation and dating of the event. Different types of indicators provide different amount of confidence and precision in determining the respective tectonic events, mainly due to the variety of their formation process and position as well as their subsequent evolution. Especially tidal notches may additionally provide information about whether a sea-level change has been gradual or coseismic, based on their profiles.

Four case studies of significant paleoseismic events are presented, all of which have greatly affected the coastal zone.

Introduction

Paleoseismology is the branch of science that aims to understand the earthquakes and their effects that have occurred in the geological past – i.e., during the Quaternary Period

(2.588 Ma to present), most commonly during the Holocene. Contributions from these past earthquakes turn out to be very critical not only to the understanding of the deformational processes within the Earth's crust but to a large extent also to develop better models for assessing seismic hazard. The main scope of this entry is to elaborate on the latter, the use of paleoseismological data in seismic hazard assessment.

Paleoseismology, also used as synonymous with "earthquake geology," has become an important and integrated part of the seismic hazard assessment during the late 1970s, following systematic work done on the San Andreas Fault in California, USA. Several studies in California (e.g., Sieh 1978; Wallace 1981, 1990; Sieh and Jahns 1984; Sieh et al. 1989; Grant and Sieh 1994; Grant and Lettis 2002) have been influential in making paleoseismology visible to other branches of Earth science. Researchers working with seismic hazard assessment became especially interested in these studies as they could see the importance of the paleoseismological data in their work. Later in the 1980s and 1990s, paleoseismological studies have spread in many other countries, most notably in Japan, Canada, New Zealand, Italy, Turkey, Greece, and Spain. In the late 1980s several monographs have contributed to a wider recognition of paleoseismology as an important field of geology (e.g., Wallace 1986; Vita-Finzi 1986; Crone and Omdahl 1987). In the late 1990s the two books published on paleoseismology by McCalpin (1996) and Yeats et al. (1997) were influential in introduction paleoseismological studies to a wider community.

Main Elements of a Paleoseismological Study

Large earthquakes occurring on crustal scale faults leave visible traces on the Earth's surface during their rupture process. This evidence on the surface is subject to both erosional and depositional processes controlled by the climatic conditions. As a consequence these evidences may either be destroyed or buried.

Paleoseismological studies are usually conducted on these faults with the aim of identifying individual paleoearthquakes with quantitative constraints on their age and size. Final aim is usually try to establish a maximum earthquake magnitude and a recurrence interval for a given fault.

Paleoseismological studies contain a number of distinct elements. They usually start with a regional analysis on the tectonic setting and structural geology of the area of interest. This is done to find out the regional deformation rates and includes geodetic strain rates obtained through the time-lap analysis of GPS data. Once the regional strain rate is known, it is possible to look for evidence at a local scale that can be expected from that rate of deformation. These regional scale studies are then followed by various types of analyses of the fault segment(s), through geological, geophysical, geodetic techniques, as well as detailed analyses of the local stratigraphy in order to select a suitable site(s) for detailed analysis. Trenching is done at the selected site(s) for identifying the paleoearthquakes. Various types of evidence are then used to identify the individual paleoearthquakes. In order to constrain the ages of these events, various dating techniques are applied on available material on event horizons within the trench stratigraphy. This is followed by establishing the slip per event and the rupture length. Based on these, finally a maximum magnitude and a recurrence interval for the fault are established. These parameters are especially important in probabilistic seismic hazard assessment (PSHA). In the following section how these parameters are integrated in seismic hazard assessment are explained.

Integrating Paleoseismological Data in Seismic Hazard Assessment

Integrating paleoseismological data in Seismic Hazard Assessment (SHA) is dependent on the type of methodology used, i.e., probabilistic (PSHA) or deterministic seismic hazard assessment (DSHA).

Paleoseismic Data and Probabilistic Seismic Hazard Assessment

Standard probabilistic seismic hazard analysis (Cornell 1968; McGuire 1993) is based on statistical treatment of earthquakes using probability density functions assuming different types of earthquake recurrence (Fig. 1). One of the most common applications of PSHA is based on a Poissonian assumption for earthquake recurrence, which assumes that the earthquake occurrence has not have memory, i.e., occurrence of earthquakes in a given area in the future has not have relation to the occurrence of previous earthquakes in the same region. Such a “random” occurrence of earthquakes is applied, not because the earthquakes do not follow a certain pattern of occurrence governed by the physical processes, but because of recognition of the fact that it is simply not always possible to assess these physical parameters that lead to stress accumulation and release process. Therefore the simple assumption of a “random” earthquake occurrence is valid, and hence it is an attempt to cover the large uncertainties associated with the complex physical processes that lead to rupture along a fault. One of the important implications of applying a recurrence relation, let it be Poissonian or other types such as conditional, exponential, Weibull, Brownian, gamma, or log-normal (e.g., Main 1995; Mathews et al. 2002), is that the complete earthquake history is known and that it represents a statistically valid sample to develop a reliable estimate of the frequency of occurrence of various magnitude

levels in a given area, the so-called Gutenberg-Richter relation.

The completeness criterion in earthquake catalogs is not always met. This is especially true in areas of low seismicity where the instrumental and historical earthquake catalogs do not cover the occurrence of large and destructive earthquakes when the recurrence time of these is beyond the limits of the total catalog time span. Using such incomplete catalogs in developing the Gutenberg-Richter relation (Fig. 2) may lead to erroneous estimate of the seismic hazard in an area. Important parameters, such as the maximum expected earthquake magnitude and its frequency of occurrence are obtained, based on the maximum observed earthquake. This may be subject to interpretation as, in many cases, simple extrapolation of the frequency-magnitude relation curve will not give realistic estimates of the maximum expected magnitude (m_2 in Fig. 2). What is usually adopted is then a truncation to the curve (m_1 in Fig. 2), whereas in reality paleoseismological data may imply a larger (or lower) level on the maximum expected magnitude (m_3 in Fig. 2). In these cases, it is essential to extend the catalog time span by investigating the earthquake occurrence in the geological past through paleoseismological studies. Extending the time span of the catalogs with the occurrence of large earthquakes in the geological past brings important constraints in establishing the maximum expected magnitude in an area.

Applying paleoseismological data to probabilistic seismic hazard assessment (Fig. 3) using

Paleoseismology: Integration with Seismic Hazard, Fig. 1 Standard probabilistic seismic hazard computations (Cornell 1968; McGuire 1993)

**Paleoseismology:
Integration with Seismic
Hazard, Fig. 2**

A hypothetical case of frequency of occurrence of earthquake magnitudes (Gutenberg-Richter relation). Crosses refer to the individual data points of the cumulative number of frequency in the earthquake catalog which is usually limited in incomplete earthquake catalogs. The different possibilities then exist in estimating the maximum expected magnitude (e.g., m_1 , m_2 , or m_3)

Paleoseismology: Integration with Seismic Hazard, Fig. 3 The use of geologic data in assessing the long-term earthquake potential (Redrawn from Schwartz and Coppersmith 1986)

time-dependent recurrence models on the other hand has typically been related to establishing the last occurrence of a large earthquake along a given fault and its recurrence in time. Together with slip rate this information is then used to develop recurrence models for the probabilistic computations. The maximum expected magnitude of a future earthquake is also used based on

the slip per event and the fault geometry together with the study of the fault segmentation and the rupture length (Schwartz and Coppersmith 1986).

Paleoseismic Data and Deterministic Seismic Hazard Assessment

While PSHA provides a useful tool for defining earthquake design loads for noncritical

Paleoseismology: Integration with Seismic Hazard, Fig. 4 A simplified sketch showing the main principles of ground motion simulations based on earthquake scenarios

including the fault rupture complexity (Courtesy of N. Pulido, 2004)

structures, especially for relatively low hazard levels (Bommer et al. 2000), in cases where the hazard is dominated by a single large earthquake from a nearby fault (e.g., Pulido et al. 2004; Sørensen et al. 2007) or if the engineering design of a critical structure requires realistic ground motions, it is preferable to perform deterministic seismic hazard assessment (DSHA). This is because in DSHA, the earthquake scenarios are defined unambiguously.

During the last decade or so, there has been a growing interest in assessing seismic hazard using ground motion simulations based on deterministic earthquake scenarios. These scenarios are usually built upon a fault rupture model where the rupture complexity is addressed either kinematically or dynamically. In kinematic models (Fig. 4) the variation of slip along the fault is modeled through predefined asperities where dynamic rupture parameters such as the rupture velocity and rise time are kept constant or varied within a given range. The obtained

ground motions for each element of the sub-faults are then propagated through a crustal velocity structure either for a simple flat-layered model or more complex 3-D structures to obtain the ground motions on the surface. The simulations can be done either for a broad frequency band using full waveform modeling for the low-frequency part of the ground motion and stochastic simulations for the high-frequency part (e.g., Pulido et al. 2004; Sørensen et al. 2007) or only using stochastic simulations (Boore 2009; Gofrani et al. 2013). Other more complicated uses of dynamic rupture models are only conducted for a few cases where data to constrain the dynamic rupture parameters as well as the three-dimensional velocity structure of the wave propagation path and the local site conditions are available (e.g., Olsen et al. 1997; Olsen 2000).

The use of paleoseismological data in developing better earthquake rupture scenarios in ground motion simulations has significant

potential which is not currently well exploited. Although most of the information regarding the fault geometry, its kinematics, rupture length, maximum magnitude, etc., is based on paleoseismological data, other constraints such as the slip distribution from past earthquakes along the fault, the location, and the size of the asperities could be better utilized in the computations. It is therefore important that paleoseismological studies focus not only on the standard parameters relevant for PSHA (e.g., maximum magnitude and recurrence interval) but also focus on other parameters, such as the location of the rupture initiation point and rupture propagation direction with its possible effects on the surface (e.g., Dor et al. 2008), as well as the details of the fault segmentation, asperities, and slip distribution.

Uncertainties in Paleoseismological Studies

Using paleoseismological data in seismic hazard assessment requires that the associated uncertainties are quantified and can be accounted for in the hazard computations. Although there are well-established methodologies that exist accounting for the various types of uncertainties (aleatory or epistemic) in seismic hazard analysis (e.g., Abrahamson and Bommer 2005), quantifying uncertainties in paleoseismic studies are usually only restricted to the analytical uncertainties associated with the age determinations. A few exceptions exist, systematically accounting for uncertainties associated with the paleoseismological (e.g., Atakan et al. 2000) and archeoseismological (Sintubin and Stewart 2008) studies.

Summary

Importance of paleoseismic data in seismic hazard assessment has been recognized since the late 1970s. There are well-established methodologies developed for integrating the paleoseismic data in probabilistic seismic hazard analysis, which usually involve extending the earthquake catalog

time span back in the geological past. This is especially true for areas of low deformation rate with sporadic seismic activity, such as plate interiors or stable continental regions, or in areas where the historical earthquake records are incomplete and scarce. The typical application of paleoseismic data in this case is associated with establishing the maximum magnitude based on the paleoearthquakes on a given fault and the recurrence in time. In seismic hazard analysis using renewal models where conditional probabilities are calculated, the occurrence of the last earthquake along a given fault as well as the magnitude and the recurrence interval are parameters that are typically used. There is however an unexploited potential of paleoseismic data in the deterministic seismic hazard studies using ground motion simulations based on earthquake rupture scenarios. The details of the slip distribution, repeated directivity effects, location and size of the asperities, as well as the rupture initiation point can be assessed by paleoseismic investigations. The use of such data in ground motion simulations requires a systematic analysis of the uncertainties associated with the paleoseismological data, not only those related to the analytical uncertainties of the age determinations but also those that are related to the interpretation of the various indices used in identifying the paleoearthquakes and their source parameters.

Automation (SMSA) Laboratory, University of
Patras, Patras, Greece

Synonyms

Fault diagnosis; Nonstationary random vibration; Signal-based modeling (identification); Structural Health Monitoring; Time-dependent ARMA modeling; Time-frequency analysis

Introduction

Nonstationary random vibration is characterized by *time-dependent (evolutionary)* characteristics (Priestley 1988; Roberts and Spanos 1990, Chapter 7; Bendat and Piersol 2000, Chapter 12; Newland 1993, pp. 211–219; Preumont 1994, Chapter 8; Hammond and White 1996; Kitagawa and Gersch 1996). Typical examples of nonstationary random vibration include earthquake ground motion and resulting structural vibration response, as well as the vibration of surface vehicles, flying aircraft, mechanisms,

rotating machinery, cranes, bridges with passing vehicles, and so on. Nonstationary random vibration typically originates from *time-varying* dynamics or the linearization of *nonlinear* dynamics.

An example of a system exhibiting nonstationary random vibration is the mechanism of Fig. 1a. It is a 2-DOF pick-and-place mechanism consisting of two coaxially aligned linear motors carrying prismatic links (arms) connected to their ends. The mechanism is clamped on an aluminum base and is excited by a zero-mean Gaussian stationary random excitation force, applied vertically with respect to the base by means of an electromechanical shaker, while the linear motors are following predetermined trajectories. The nonstationary nature of the resulting vibration (see Fig. 1b) is due to the time-varying position of the linear motors, thus controlling the position of the links, and is evident in the time-varying power spectral density (TV-PSD) parametric estimate of Fig. 1c. Further details on this example may be found in (Spiridonakos and Fassois 2013).

From a mathematical point of view, nonstationary random vibration is characterized by time-dependent statistical moments. In the presently assumed *Gaussian* case, this means that the mean is a function of time t and the autocovariance function (ACF) a function of two time arguments t_1 and t_2 . That is, for a random vibration signal $x(t)$, one has $E\{\cdot\}$ designates statistical expectation)

$$\begin{aligned}\text{Mean : } \mu(t) &= E\{x(t)\}, \\ \text{ACF : } \gamma(t_1, t_2) &= E\{(x(t_1) - \mu(t_1)) \cdot (x(t_2) - \mu(t_2))\} \\ &\quad (1)\end{aligned}$$

In many random vibration problems, the mean is constant and is thus easily estimated and removed from the signal (sample-mean adjusted signal). The case of a time-dependent mean (also referred to as deterministic trend) may be treated via proper techniques, such as curve fitting, high-pass filtering, or special parametric models (such as integrated models with a deterministic trend parameter (Box et al. 1994)).

Parametric Nonstationary Random Vibration Modeling with SHM Applications, Fig. 1 Example of a laboratory pick-and-place mechanism exhibiting nonstationary random vibration: (a) schematic diagram

of the mechanism and the laboratory setup; (b) measured vibration acceleration response signal (normalized); (c) estimate of the TV-PSD (time-frequency spectrum)

This entry focuses on the following two subjects: (i) The signal-based modeling (identification) of nonstationary random vibration based on a uniformly sampled (with sampling period T) signal realization $x[t]$, for $t = 1, 2, \dots, N$. Absolute time is $t \cdot T$, N is the signal length in samples, while the use of brackets indicates function of an integer variable. (ii) The use of an identified random vibration model (or in fact a set of such models) for Structural Health Monitoring (SHM), where the objective is the *detection* of potential structural damage and its *characterization (identification)* (Fassois and Sakellariou 2009). Other important uses of an identified model – not discussed in this entry – include model-based analysis (like the extraction of time-dependent power spectral density (PSD) and time-dependent vibration modes (Newland 1993, p. 218; Preumont 1994, Chapter 8; Poulimenos and Fassois 2006)), prediction, classification, and control.

Nonstationary random vibration signal-based modeling (identification) has received significant attention in recent years. The available methods may be broadly classified as *parametric* or *nonparametric* (Poulimenos and Fassois 2006).

Nonparametric methods have received most of the attention and are based upon nonparameterized representations of the vibration energy as a simultaneous function of time and frequency (time-frequency representations). They include the classical spectrogram (based upon the short-time Fourier transform – STFT) and its ramifications (Newland 1993, p. 218; Hammond and White 1996; Bendat and Piersol 2000, p. 504), Mark's physical spectrum (Preumont 1994, Section 8.3), the Cohen class of distributions (Hammond and White 1996), Priestley's evolutionary spectrum (Priestley 1988, Section 6.3; Preumont 1994, Section 8.4), as well as wavelet-based methods (Newland 1993, Chapter 17). On the other hand, *parametric methods* are based upon parameterized representations, usually of the *time-dependent autoregressive moving average (TARMA)* type. These have an apparently similar form to their conventional (stationary) counterparts, but are characterized by *time-dependent* parameters and innovations variance. Thus, a $TARMA(n_a, n_c)$ model, with n_a and n_c designating its AR and MA orders, respectively, is defined as follows (Poulimenos and Fassois 2006):

TARMA(n_a, n_c) model :

$$x[t] = -\sum_{i=1}^{n_a} a_i[t]x[t-i] + \sum_{i=1}^{n_c} c_i[t]w[t-i] + w[t];$$

$$w[t] \sim \text{NID}(0, \sigma_w^2[t])$$
(2)

where $x[t]$ represents the nonstationary random signal model; $w[t]$ an unobservable *normally and independently distributed* (NID) (thus *white*) nonstationary *innovations* sequence with zero-mean and time-dependent variance $\sigma_w^2[t]$; n_a, n_c the autoregressive (AR) and moving average (MA) orders, respectively; and $a_i[t]$ and $c_i[t]$ the corresponding AR and MA *time-dependent parameters*.

Parametric TARMA models are of three main families, according to the form of “structure” imposed upon the evolution of the time-dependent parameters and innovations variance (Poulimenos and Fassois 2006):

- (a) *Unstructured parameter evolution (UPE)* models, in which no particular “structure” is imposed on the parameter evolution. Prime models in this family include short-time ARMA (ST-ARMA) and recursive models (such as recursive ARMA or in short RARMA) models.
- (b) *Stochastic parameter evolution (SPE)* models, in which *stochastic* “structure” is imposed on the parameter evolution via stochastic smoothness constraints. Prime models in this family include smoothness-priors ARMA (SP-ARMA) models.
- (c) *Deterministic parameter evolution (DPE)* models, in which deterministic “structure” is imposed on the parameter evolution. Prime models in this family include the so-called functional series TARMA (FS-TARMA) models in which the parameters are projected on properly selected functional subspaces.

Parametric models, and their respective signal-based (identification) methods, are known to be characterized by a number of important advantages, such as representation parsimony, improved accuracy and resolution,

improved tracking of the TV dynamics, flexibility in analysis, synthesis (simulation), prediction, diagnosis, and control. For instance, once a TARMA model is available, the corresponding “frozen”-type TV-PSD may be readily obtained as

“Frozen” TV-PSD :

$$S_F(\omega, t) = \frac{\left| 1 + \sum_{i=1}^{n_c} c_i[t] \cdot e^{-j\omega T_{si}} \right|^2}{\left| 1 + \sum_{i=1}^{n_a} a_i[t] \cdot e^{-j\omega T_{si}} \right|^2} \cdot \sigma_w^2[t]$$
(3)

with ω representing frequency in *rad/s*, j the imaginary unit, and $|\cdot|$ complex magnitude. Notice that this would be the PSD of the vibration signal if the system were “frozen” (made stationary) at each time instant t . This entry focuses on parametric models and methods and in particular on the SPE and DPE families.

The problem of Structural Health Monitoring (SHM) for structures exhibiting nonstationary random vibration responses may be treated in a statistical time series (STS) framework (Fassois and Sakellariou 2009), using either nonparametric or parametric models and statistical decision-making schemes. In the majority of applications thus far, nonparametric models (nonparametric time-frequency-type representations) are used, and damage detection and identification are based on potential discrepancies observed between those obtained in a *baseline* (healthy) phase and an *inspection* (current) phase (Feng et al. 2013). Although the use of parametric models and methods may potentially lead to performance improvements, it has thus far received limited attention (Poulimenos and Fassois 2004; Spiridonakos and Fassois 2013).

Brief Historical Notes. Among parametric models, the unstructured parameter evolution (UPE) family of methods was initially developed. Prime methods in this area include the short-time ARMA (ST-ARMA) method (Niedzwieki 2000, pp. 79–82; Owen et al. 2001) and the class of recursive (or adaptive) methods (Ljung 1999, Chapter 11; Niedzwieki 2000, Chapters 4 and 5).

The stochastic parameter evolution (SPE) family of methods was developed primarily for the modeling of earthquake ground motion signals (Kitagawa and Gersch 1996; Gersch and Akaike 1988). The deterministic parameter evolution (DPE) family was introduced in a broader context in Rao (1970) and later in Kozin (1977). In Kozin (1988) and Fouskitakis and Fassois (2002) it was employed for earthquake ground motion modeling. In Poulimenos and Fassois (2009b) it was applied to the vibration of a bridge-like structure with a moving mass. In a broader context the reader is also referred to (Niedzwieki 2000, Chapter 4).

Article Roadmap. This entry is organized as follows: SPE and DPE nonstationary random vibration modeling is discussed in section “[Parametric TARMA Modeling of Nonstationary Random Vibration](#),” where specific model forms and identification schemes are briefly reviewed. Structural Health Monitoring (SHM) based on nonstationary random vibration parametric modeling is presented in section “[Structural Health Monitoring \(SHM\) Based on Nonstationary Random Vibration](#).” The application of these concepts to random vibration modeling and SHM for the pick-and-place mechanism of Fig. 1 is outlined in section “[Illustrative Example: Nonstationary Random Vibration Modeling and SHM for a Pick-and-Place Mechanism](#),” while a summary is provided in section “[Summary](#).”

Parametric TARMA Modeling of Nonstationary Random Vibration

Stochastic Parameter Evolution (SPE) TARMA Modeling

In the context of *stochastic parameter evolution (SPE)* TARMA models, the parameters are assumed to follow *stochastic smoothness constraints* in the form of linear integrated autoregressive (IAR) models with integration order q (in this context referred to as *smoothness-priors order*). A *smoothness-priors* TARMA (SP-TARMA) model thus has parameters that obey the relations (Kitagawa and Gersch 1996)

$$(1 - B)^q \cdot a_i[t] = v_{ai}[t], \quad v_{ai}[t] \sim \text{NID}(0, \sigma_v^2) \quad (4a)$$

$$(1 - B)^q \cdot c_i[t] = v_{ci}[t], \quad v_{ci}[t] \sim \text{NID}(0, \sigma_v^2) \quad (4b)$$

where the signal innovations $w[t]$ (see Eq. 2) and the parameter innovations $v_{ai}[t]$ and $v_{ci}[t]$ are all mutually independent and normally and identically distributed (NID) sequences, each being zero mean and with variance $\sigma_w^2[t]$ and σ_v^2 , respectively. These smoothness constraints are characterized by unit roots that represent integrated stochastic models describing homogeneously nonstationary evolutions (Box et al. 1994, Chapter 4).

Generalization of SP-TARMA models, in the form of *generalized stochastic constraint time-dependent autoregressive moving average* TARMA (GSC-TARMA) models, was recently introduced (Avendaño-Valencia and Fassois 2013). In this, the model parameters are allowed to follow more general autoregressive (AR) models of the forms

$$a_i[t] = -\sum_{k=1}^q \mu_k \cdot a_i[t-k] + v_{ai}[t], \quad (5a)$$

$$v_{ai}[t] \sim \text{NID}(0, \sigma_v^2)$$

$$c_i[t] = -\sum_{k=1}^q \mu_k \cdot c_i[t-k] + v_{ci}[t], \quad (5b)$$

$$v_{ci}[t] \sim \text{NID}(0, \sigma_v^2),$$

where, as in the SP-TARMA case, $w[t]$, $v_{ai}[t]$, and $v_{ci}[t]$ are mutually independent and normally and identically distributed (NID) innovation sequences. The coefficients μ_k are referred to as the *stochastic constraint parameters*. These are collected in the vector $\boldsymbol{\mu} = [\mu_1 \cdot \dots \cdot \mu_q]^T$, which is along with the covariance $\boldsymbol{\Sigma}_v = \sigma_v^2 \cdot \mathbf{I}_{n_a+nc}$ (where $\mathbf{I}_{n_a+nc}$ is the identity matrix with the indicated dimensions), and the innovations variance $\sigma_w^2[t]$ defines the model *hyperparameters*. Then the time-dependent AR/MA parameters $\boldsymbol{\theta}[t]$, hyperparameters $\mathcal{P}$, and structural parameters $\mathcal{M}$ of a GSC-TARMA model are

$$\begin{aligned}\boldsymbol{\theta}[t] &= [a_1[t] \cdots a_{n_a}[t] \vdots c_1[t] \cdots c_{n_c}[t]]^T, \\ \mathcal{P} &= \{\boldsymbol{\mu}, \sigma_w^2[t], \boldsymbol{\Sigma}_v\}, \quad \mathcal{M} = \{n_a, n_c, q\}\end{aligned}\quad (6)$$

It should be noted that the stochastic constraint parameters and parameter innovations variances may be – more generally – different for each AR/MA parameter, but the above simple form is adopted here for purposes of presentation simplicity. Comparing the GSC-TARMA and SP-TARMA model forms, one sees that in the latter case the stochastic constraint parameters are essentially prefixed, limiting the types of trajectories that each AR/MA parameter would be capable of following.

The identification of an SP-TARMA or GSC-TARMA model consists of the selection of the model structure $\mathcal{M}$ and the estimation of the time-dependent parameter vector $\boldsymbol{\theta}[t]$ and hyperparameters $\mathcal{P}$. The estimation of the model parameters and hyperparameters may be posed as the maximization of the *joint a posteriori probability* density function of $\boldsymbol{\theta}_1^N = \{\boldsymbol{\theta}[1], \dots, \boldsymbol{\theta}[N]\}$ given the available observations $x_1^N = \{x[1], \dots, x[N]\}$, namely, $p(\boldsymbol{\theta}_1^N, \mathcal{P} | x_1^N)$. These, combined with the Gaussianity assumption for $w[t]$ and

$\mathbf{v}[t] = [v_{a_1}[t] v_{a_2}[t] \cdots v_{c_{n_c}}[t]]^T$, lead to the following cost function:

$$\begin{aligned}\mathcal{J}(\boldsymbol{\theta}_1^N, \mathcal{P}) &= \frac{N \cdot q \cdot (n_a + n_c)}{2} \ln |\sigma_v^2| \\ &\quad + \frac{1}{2} \sum_{t=1}^N \left(\ln \sigma_w^2[t] + \frac{w^2[t]}{\sigma_w^2[t]} + \frac{\mathbf{v}^T[t] \cdot \mathbf{v}[t]}{\sigma_v^2} \right)\end{aligned}\quad (7)$$

which must be minimized in order to provide the optimal *maximum a posteriori* (MAP) estimate of $\boldsymbol{\theta}[t]$ and $\mathcal{P}$.

An estimate of $\boldsymbol{\theta}[t]$ based on fixed values of $\mathcal{P}$ may be obtained recursively using the Kalman filter (or a proper nonlinear approximation filter in the full TARMA case) based on the following state-space representation of the SP/GSC-TARMA model (Poulimenos and Fassois 2006):

$$\mathbf{z}[t] = \mathbf{F}(\boldsymbol{\mu}) \cdot \mathbf{z}[t-1] + \mathbf{G} \cdot \mathbf{v}[t] \quad (8a)$$

$$x[t] = \mathbf{h}^T[t] \cdot \mathbf{z}[t] + w[t] \quad (8b)$$

with:

$$\begin{aligned}\mathbf{z}[t-1] &= \begin{bmatrix} \boldsymbol{\theta}[t-1] \\ \boldsymbol{\theta}[t-2] \\ \vdots \\ \boldsymbol{\theta}[t-q] \end{bmatrix}, \quad \mathbf{F}(\boldsymbol{\mu}) = \begin{bmatrix} \mu_1 & \mu_2 & \cdots & \mu_{q-1} & \mu_q \\ 1 & 0 & \cdots & 0 & 0 \\ 0 & 1 & \cdots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & 1 & 0 \end{bmatrix} \otimes \mathbf{I}_{n_a+n_c}, \\ \mathbf{G} &= \begin{bmatrix} 1 \\ 0 \\ \vdots \\ 0 \end{bmatrix} \otimes \mathbf{I}_{n_a+n_c}, \quad \mathbf{h}[t] = \begin{bmatrix} \mathbf{x}[t-1] \\ \mathbf{w}[t-1] \\ 0 \\ \vdots \\ 0 \end{bmatrix}\end{aligned}$$

where $\mathbf{x}[t-1] = [x[t-1] x[t-2] \cdots x[t-n_a]]^T$ and $\mathbf{w}[t-1] = [w[t-1] w[t-2] \cdots w[t-n_c]]^T$. Notice that in estimation and in the full TARMA case, the innovations $w[t]$ may be replaced by their respective a posteriori estimates $\hat{w}[t] = x[t] - \mathbf{h}^T[t] \cdot \hat{\mathbf{z}}[t]$,

where $\hat{\mathbf{z}}[t]$ is the a posteriori state estimate (Niedzwieki 2000, p. 263). After initial estimation with the Kalman filter, refined parameter estimates may be obtained by using the Kalman smoother (Poulimenos and Fassois 2006).

The estimation of an SP-TARMA model is performed by computing θ_1^N as described above, using fixed values of σ_w^2 and σ_v^2 . Since the values of these variances are generally unavailable, a *normalized* form of the Kalman filter may be used, where the prediction/update equations are divided by σ_w^2 . In this way, a single parameter $\lambda = \sigma_v^2/\sigma_w^2$ is left as a design (user selected) parameter that adjusts the “tracking speed” versus “smoothness of the estimates” in the algorithm (Poulimenos and Fassois 2006).

In the GSC-TARMA case, an expectation-maximization scheme can be used as follows (Avenidaño-Valencia and Fassois 2013): (i) *expectation step*: obtain $\theta[t]$ using the Kalman filter as previously described, based on fixed values of $\mathcal{P}$; (ii) *maximization step*: estimate μ and $\sigma_w^2[t]$ based on the estimated values of $\theta[t]$. The E and M steps are sequentially repeated until convergence of the cost function $\mathcal{J}(\theta_1^N, \mathcal{P})$ is achieved. The estimation of σ_v^2 is avoided within the M step, as it destabilizes the algorithm. Thus, as in the SP-TARMA case, σ_v^2 is left as a design parameter to adjust the tracking speed and the parameter smoothness.

For both SP and GSC-TARMA models, the selection of the value of σ_v^2 may not be straightforward, since a very low value may over-smooth the estimated parameter trajectories, while a high value may lead to “noisy” trajectories. The selection of σ_v^2 may be guided by comparing the innovations (prediction residuals) with the parameter innovations (prediction error of the parameters) – that is, the *residual sum of squares* (RSS) to the *parameter prediction error sum of squares* (PESS):

$$RSS = \sum_{t=1}^N \hat{w}^2[t], \quad PESS = \sum_{t=1}^N \hat{v}^T[t] \cdot \hat{v}[t] \quad (9)$$

where $\hat{w}[t] = x[t] - \mathbf{h}^T[t] \cdot \hat{\mathbf{z}}[t|t-1]$ stands for the one-step-ahead prediction error (residual) at time t and $\hat{v}[t] = \hat{\theta}[t|t] - \hat{\theta}[t|t-1]$ is an estimate of the parameter innovations with $\hat{\theta}[t|t-1]$ being the a priori and $\hat{\theta}[t|t]$ the a posteriori Kalman filter estimates of $\theta[t]$. Both RSS and PESS are computed from the Kalman filter predictions of

$w[t]$ and $v[t]$ obtained for a specific value of σ_v^2 . A high RSS indicates poor modeling accuracy, whereas high PESS indicates noisy parameter estimates. A curve displaying the PESS versus the RSS (parameterized in terms of σ_v^2) may be constructed and used for selecting a good compromise (and hence a proper σ_v^2).

Remarks: (i) In the definition of the GSC-TARMA model, it is also possible to include a stochastically time-dependent innovations variance, as in Kitagawa and Gersch (1996). (ii) Additional definitions are possible for the general SPE-TARMA model class. For instance non-Gaussian signals or nonlinear stochastic parameter evolution dynamics may be included, which may be appropriate for some rapidly evolving processes (Kitagawa and Gersch 1996).

Deterministic Parameter Evolution (DPE) TARMA Modeling

DPE-TARMA models are typically defined in terms of the *functional series TARMA* (FS-TARMA) model form, for which the temporal evolution of the parameters is expressed via projections in proper functional subspaces. Thus, for an FS-TARMA $(n_a, n_c)_{[p_a, p_c, p_s]}$ model, with p_a, p_c, p_s designating its AR, MA, and innovations variance functional subspace dimensionalities, the evolution of the parameters is as follows (Poulimenos and Fassois 2006):

$$\begin{aligned} a_i[t] &= \sum_{k=1}^{p_a} a_{i,k} \cdot G_{b_{a(k)}}[t], \quad c_i[t] = \sum_{k=1}^{p_c} c_{i,k} \cdot G_{b_{c(k)}}[t], \\ \sigma_w^2[t] &= \sum_{k=1}^{p_s} s_k \cdot G_{b_{s(k)}}[t] \end{aligned} \quad (10a)$$

$$\begin{aligned} \mathcal{F}_{AR} &= \{G_{b_{a(1)}}[t], \dots, G_{b_{a(p_a)}}[t]\}, \\ \mathcal{F}_{MA} &= \{G_{b_{c(1)}}[t], \dots, G_{b_{c(p_c)}}[t]\}, \\ \mathcal{F}_{\sigma_w^2[t]} &= \{G_{b_{s(1)}}[t], \dots, G_{b_{s(p_s)}}[t]\} \end{aligned} \quad (10b)$$

with “ $\mathcal{F}$ ” designating the functional subspace of the indicated quantity; $b_{a(k)}$ ($k = 1 \dots, p_a$), $b_{c(k)}$

($k = 1 \dots, p_c$), and $b_{s(k)}$ ($k = 1 \dots, p_s$) indices indicating the specific basis functions included in each subspace; and $a_{i,k}$, $c_{i,k}$, and s_k the AR, MA, and innovations variance, respectively, *coefficients of projection*. Thus, for an FS-TARMA model the model parameter vector is $\boldsymbol{\vartheta} = [\boldsymbol{\vartheta}_a^T \boldsymbol{\vartheta}_c^T \boldsymbol{\vartheta}_s^T]^T$, while model structure is specified by the AR and MA orders n_a, n_c and the AR, MA, and innovations variance basis function index vectors $\mathbf{b}_a = [b_{a(1)} \dots b_{a(p_a)}]^T$, $\mathbf{b}_c = [b_{c(1)} \dots b_{c(p_c)}]^T$, and $\mathbf{b}_s = [b_{s(1)} \dots b_{s(p_s)}]^T$, that is,

$$\begin{aligned} \boldsymbol{\vartheta} &= [\boldsymbol{\vartheta}_a^T \boldsymbol{\vartheta}_c^T \boldsymbol{\vartheta}_s^T]^T \\ &= [a_{1,1} \dots a_{n_a,p_c} | c_{1,1} \dots c_{n_c,p_c} | s_1 \dots s_{p_s}]^T \end{aligned} \quad (11a)$$

$$\mathcal{M} = \{n_a, n_c, \mathbf{b}_a, \mathbf{b}_c, \mathbf{b}_s\} \quad (11b)$$

In a recent extension, adaptable FS-TARMA (AFS-TARMA) models that employ functional subspaces parameterized by a parameter vector $\boldsymbol{\delta}$ were introduced (Spiridonakos and Fassois 2014a). The model definition is as in Eq. 10, but the functional bases are parameterized according to the following forms: $\mathcal{F}_{AR} = \{G_{b_{a(1)}}[t, \boldsymbol{\delta}_a], \dots, G_{b_{a(p_a)}}[t, \boldsymbol{\delta}_a]\}$, $\mathcal{F}_{MA} = \{G_{b_{c(1)}}[t, \boldsymbol{\delta}_c], \dots, G_{b_{c(p_c)}}[t, \boldsymbol{\delta}_c]\}$, and $\mathcal{F}_{\sigma_w^2[t]} = \{G_{b_{s(1)}}[t, \boldsymbol{\delta}_s], \dots, G_{b_{s(p_s)}}[t, \boldsymbol{\delta}_s]\}$, where $\boldsymbol{\delta}_a$, $\boldsymbol{\delta}_c$, and $\boldsymbol{\delta}_s$ indicate the AR, MA, and innovations variance functional subspace parameter vector, respectively. The model structure is in this case defined by just the model orders and functional subspace dimensionalities, while the complete parameter vector includes the functional subspace parameters as well:

$$\begin{aligned} \boldsymbol{\theta} &= [\boldsymbol{\vartheta}^T \boldsymbol{\delta}^T]^T, \quad \boldsymbol{\delta} = [\boldsymbol{\delta}_a^T \boldsymbol{\delta}_c^T \boldsymbol{\delta}_s^T]^T, \\ \mathcal{M} &= \{n_a, n_c, p_a, p_c, p_s\} \end{aligned} \quad (12)$$

The advantage of the AFS-TARMA model structure is that the selection of the basis functions, which is a structural problem in conventional FS-TARMA models, becomes part of the parameter estimation problem and is thus

significantly simplified. The adaptable models may thus better “adapt” to a given nonstationary signal, while the modeling procedure is easier for the user.

The estimation of AFS/FS-TARMA models is typically accomplished within a *maximum likelihood* (ML) framework. In the FS-TARMA case, and under Gaussian innovations, the log-likelihood function is (Spiridonakos and Fassois 2014b)

$$\begin{aligned} \ln \mathcal{L}(\boldsymbol{\vartheta} | x_1^N) &= -\frac{N}{2} \cdot \ln 2\pi \\ &\quad - \frac{1}{2} \sum_{t=1}^N \left(\ln \sigma_w^2[t] + \frac{w^2[t]}{\sigma_w^2[t]} \right) \end{aligned} \quad (13)$$

As the likelihood function in Eq. 13 is non-quadratic in terms of the unknown parameter vector, the maximization is based on iterative schemes and rather accurate initial parameter estimates are required for avoiding potential local extrema.

In the simpler case of FS-TAR models, initial parameter values may be obtained by estimating $\boldsymbol{\vartheta}_a$ via *ordinary least squares* (OLS) and subsequently estimating $\boldsymbol{\vartheta}_s$ via an overdetermined set of equations after estimating $\sigma_w^2[t]$ via a sliding window approach (Poulimenos and Fassois 2006). In the FS-TARMA case more elaborate techniques are necessary, as the prediction error is a nonlinear function of the projection coefficient vector $\boldsymbol{\vartheta}_c$. These include *linear multistage* or *recursive* methods (Poulimenos and Fassois 2006). Linear multistage methods first obtain an initial *estimate* of the prediction error sequence based on high-order TAR models and subsequently employ the obtained values to estimate the FS-TARMA model coefficients of projection (the two-stage least-squares (2SLS) approach). Recursive methods use the recursive extended least squares (RELS) or the recursive maximum likelihood (RML) algorithms to obtain initial coefficient of projection estimates (Poulimenos and Fassois 2006). Several runs over the data are typically recommended to avoid the influence of the unknown initial conditions and ensure convergence of the algorithm. For adaptable

(AFS-TARMA) models, an estimation scheme based on separable nonlinear least squares (SNLS), in which the vectors $\boldsymbol{\vartheta}$ and $\boldsymbol{\delta}$ are estimated separately in an sequential fashion, has been suggested (Spiridonakos and Fassois 2014a, b). The reader is referred to (Poulimenos and Fassois 2006; Spiridonakos and Fassois 2014b) for further details on AFS/FS-TARMA models and their estimation.

Remarks: (i) For conventional FS-TARMA models, the functional subspaces include linearly independent basis functions selected from an ordered set, such as Chebyshev, trigonometric, b-splines, wavelets, and other functions. For simplicity a functional subspace is often selected to include consecutive basis functions up to a maximum index. Yet, for purposes of model parsimony (economy) and effective estimation, some functions may not be necessary and may be dropped. (ii) An FS-TARMA $(n_a, n_c)_{[p_a, p_c, p_s]}$ model of the form (10) is referred to as a *fully parametric* FS-TARMA model. The term *semi-parametric* FS-TARMA $(n_a, n_c)_{[p_a, p_c]}$ model implies that the innovations variance is not parameterized, that is, it is not projected on a functional subspace.

Model Structure Selection

Model structure selection is the process by which the structural parameters of the model are obtained. This is typically an iterative and tedious procedure, in which models corresponding to various candidate structures are first estimated, and the one providing the *best fitness* is selected. This procedure may be facilitated via integer optimization schemes or backward/forward regression schemes (Spiridonakos and Fassois 2014b). Model fitness may be judged in terms of a number of criteria, which may include the residual sum of squares (RSS) (often normalized by the series sum of squares, SSS), the likelihood function, and the Akaike information criterion (AIC) or the Bayesian information criterion (BIC). The latter two are typically preferred as they maintain a balance between model fit (model accuracy) and model size (thus discouraging overfitting). The RSS/SSS and BIC criteria are defined as

$$\begin{aligned} \text{RSS/SSS} &= \sum_{t=1}^N \hat{w}^2[t] / \sum_{t=1}^N x^2[t], \\ \text{BIC} &= -\ln \mathcal{L}(\cdot) + \frac{\ln N}{2} \cdot d \end{aligned} \quad (14)$$

where $\hat{w}[t]$ is the obtained one-step-ahead prediction error at time t , $\mathcal{L}(\cdot)$ is the likelihood of the respective model family, and d is the number of estimated parameters in the model (FS-TARMA, $d = \dim \boldsymbol{\vartheta}$; AFS-TARMA, $d = \dim \boldsymbol{\theta}$; SPE-TARMA, $d = \dim z[t] = (n_a + n_c) \cdot q$) (Poulimenos and Fassois 2006; Kitagawa and Gersch 1996, Chapter 2). Notice that in the DPE-TARMA case, the likelihood is defined by Eq. 13, while in the SPE-TARMA case the log-likelihood function (w.r.t. the hyperparameters) is equivalent to $\mathcal{J}(\hat{\boldsymbol{\theta}}_1^N, \hat{\mathcal{P}})$ (Avendaño-Valencia and Fassois 2013).

It should be noted that model estimation always requires attention on part of the user in order to detect numerical problems (for instance, those due to inverting an ill-conditioned matrix) or estimating a number of parameters that is not commensurate with the signal length. As a rough guide, the number of signal samples per estimated parameter (SPP) should be at least 15 (Spiridonakos and Fassois 2014b). Finally formal *model validation* – which examines the validity of the model assumptions (such as innovations whiteness and Gaussianity) – should be performed before final model acceptance (Box et al. 1994, Chapter 8; Poulimenos and Fassois 2006; Spiridonakos and Fassois 2014b).

Structural Health Monitoring (SHM) Based on Nonstationary Random Vibration

Let s_v designate a given structure in one of several potential health states. $v = o$ designates the healthy state, while any other v from the set $V = \{a, b, \dots\}$ designates the structure in a damaged (faulty) state of a distinct *type* $a, b, \dots$ and so forth (for instance, damage in a particular region, or of a particular nature).

In general, each damage type may include a continuum of damages, each being characterized by its own damage *magnitude*.

The SHM problem may be then posed as follows: Given the structure in a currently *unknown* state u , first determine whether or not the structure is damaged ($u = o$ or $u \neq o$) (the *damage detection subproblem*). In case the structure is found to be damaged, determine which one of $\{a, b, \dots\}$ is the current damage type (the *damage identification subproblem*). The *damage magnitude estimation subproblem*, which focuses on estimating the magnitude of the current damage, will not be treated in this entry.

When the main information available for solving this problem is in the form of measured structural vibration response, then the problem is classified as a *vibration-based* SHM problem. If additional information – such as an analytical structural dynamics model – is used for its solution, then the method is classified as *analytical model based*, otherwise as a *data based*. This entry focuses in the latter case where analytical models are not available or are hard to obtain – the reader is referred to Fassois and Sakellariou (2009) and Farrar and Worden (2013) for a broader overview and details. In the context of this entry, the important – but obviously more difficult and scarcely studied – case of *nonstationary* random vibration is considered.

From an operational viewpoint, vibration-based SHM is organized into two distinct phases: First, an initial *baseline phase* in which a set of vibration response signals $x_v[t]$ ($t = 1, \dots, N$), possibly for all $v \in \{o, a, b, \dots\}$, are obtained and properly processed (this phase is carried out only once). Second, an *inspection phase* in which (typically) a single vibration response signal $x_u[t]$ is obtained and decisions on the presence and type of damage need to be made (the aforementioned damage detection and identification subproblems). This phase is typically carried out continuously or periodically, each time using a fresh vibration signal.

In this entry two SHM approaches are presented within a nonstationary random vibration context: a *parameter-based* one and a *residual-based* one. Both are based on the modeling of the nonstationary random vibration signals via the earlier discussed FS-TARMA representations. For purposes of simplicity, the damage identification subproblem is treated via successive binary hypothesis testing (instead of a single multiple hypothesis testing). In this (former) context, once the presence of damage is detected, its type is determined via successive (pairwise) comparisons with each potential damage type. An implicit assumption behind both approaches is that the operating and measurement conditions in the baseline and inspection phases are *identical*. Hence, the various signals correspond to each other in a proper way – in particular in their time duration they describe the exact same motion or operational cycle.

A Parameter-Based Approach

The essence of this approach is on the use of the projection coefficient vector $\boldsymbol{\vartheta}$ of an FS-TARMA model of the nonstationary random vibration as the *characteristic quantity (or feature)* in the decision-making mechanism. The underlying thesis is that each distinct health state is characterized by its own projection coefficient vector, thus “comparing” that of the current state u to that of the healthy state o leads to damage detection. In the positive (damage) case, “comparing” that of the current state u sequentially (pairwise) to that of each damage state $\{a, b, \dots\}$ leads to damage identification.

Hence, in the (initial) baseline phase FS-TARMA models corresponding to the healthy o and each damage state $\{a, b, \dots\}$ are estimated. Then, in the (current) inspection phase, an (identical in structure) FS-TARMA model corresponding to the current structural state u is estimated based on the currently available vibration signal. Then damage detection may be treated via a hypothesis test of the form

$$\begin{aligned} H_0 : \boldsymbol{\vartheta}_o - \boldsymbol{\vartheta}_u &= \mathbf{0} && \text{Null hypothesis – healthy state} \\ H_1 : \boldsymbol{\vartheta}_o - \boldsymbol{\vartheta}_u &\neq \mathbf{0} && \text{Alternative hypothesis – damaged state} \end{aligned}$$

As the true coefficient of projection vectors are not available, decision making is based on corresponding estimates $\hat{\boldsymbol{\vartheta}}_o$ and $\hat{\boldsymbol{\vartheta}}_u$, and since these are random quantities, on their distributions. In this context, under mild assumptions, the estimators are shown to be asymptotically (for “long” data records, i.e., $N \rightarrow \infty$) Gaussian distributed, with mean equal to the true coefficient of projection vector and covariance Σ that

may be estimated (Poulimenos and Fassois 2009a; Spiridonakos and Fassois 2013). Under these conditions, the quantity d_M^2 , below, follows (assuming negligible variability for the covariance estimator) chi-square distribution with d degrees of freedom ($d = \dim \boldsymbol{\vartheta}$). Hence, decision making may be made as follows at the α risk level (i.e., false alarm probability equal to α):

$$d_M^2 = \left(\hat{\boldsymbol{\vartheta}}_u - \hat{\boldsymbol{\vartheta}}_o \right)^T \cdot \hat{\Sigma}_o^{-1} \cdot \left(\hat{\boldsymbol{\vartheta}}_u - \hat{\boldsymbol{\vartheta}}_o \right) \leq \chi_d^2(1 - \alpha) \Rightarrow \text{Accept } H_0 \quad (15)$$

otherwise $\Rightarrow \text{Accept } H_1$

with $\chi_d^2(1 - \alpha)$ designating the $1 - \alpha$ critical point of the chi-square distribution (d degrees of freedom) and $\hat{\Sigma}_o$ the estimator covariance in the healthy case. As already indicated, damage identification may be treated via similar pairwise tests in which the current true coefficient of projection vector $\boldsymbol{\vartheta}_u$ is compared to the true vector $\boldsymbol{\vartheta}_v$, corresponding to each damage state (for $v \in \{a, b, \dots\}$). Of course, ramifications of the method are possible, for instance, by only including specific elements of the coefficient of projection vector, or a properly transformed (for instance, via principal component analysis) version. An obvious disadvantage of the general parameter-based approach is that model estimation needs to be carried out in the inspection phase as well.

A Residual-Based Approach

The essence of this approach is on the use of the FS-TARMA model residual signal $\hat{w}[t]$, and more specifically its time-dependent variance $\sigma_w^2[t]$, as the *characteristic quantity* (or *feature*) in the decision-making mechanism. The underlying thesis is that for each distinct health state (for instance,

the healthy state), the model residual signal (then $\hat{w}_o[t]$) is characterized by its own residual variance (then $\sigma_{w_o}^2[t]$) – this may be obtained in the baseline phase. Then, under the hypothesis that the structure is still in the same health state during inspection, the new residual signal ($\hat{w}_u[t]$) obtained by driving the *current* (fresh) vibration signal ($x_u[t]$) through the *same baseline model* (no model reestimation involved) should be characterized by the same time-dependent variance (then $\sigma_{w_o}^2[t]$) *if and only if* the hypothesis of the structure being in the same health state (for instance, healthy state) is correct (as a change would result in increased variance). Then, a decision on the health state of the structure may be made based on comparing the current time-dependent residual variance ($\sigma_{w_u}^2[t]$) to the baseline time-dependent variance (then $\sigma_{w_o}^2[t]$) at each time instant. Of course, this procedure may be repeated for any other health state of the structure in the baseline phase for binary *damage identification*.

Then damage detection may be treated via a hypothesis test of the form (Poulimenos and Fassois 2004):

$$\begin{array}{ll} H_0 : \sigma_{w_u}^2[t] \leq \sigma_{w_o}^2[t] & \text{Null hypothesis – healthy state} \\ H_1 : \sigma_{w_u}^2[t] > \sigma_{w_o}^2[t] & \text{Alternative hypothesis – damaged state} \end{array}$$

As the theoretical variances $\sigma_{w_u}^2[t]$ and $\sigma_{w_o}^2[t]$ are unavailable, they need to be estimated from the

obtained residual series $\hat{w}_u[t]$ and $\hat{w}_o[t]$ using a moving average filter (sliding window) as follows:

$$\begin{aligned}\hat{\sigma}_{w_u}^2[t] &= \frac{1}{\ell} \sum_{\tau=t-(\ell-1)/2}^{t+(\ell-1)/2} \hat{w}_u^2[\tau], \\ \hat{\sigma}_{w_o}^2[t] &= \frac{1}{\ell_o} \sum_{\tau=t-(\ell_o-1)/2}^{t+(\ell_o-1)/2} \hat{w}_o^2[\tau]\end{aligned}\quad (16)$$

with ℓ , ℓ_o designating the corresponding window lengths. Under the null hypothesis (H_0), given the residual normality and uncorrelatedness, the statistic defined as the ratio of the two variance estimators follows an F distribution with $(\ell - 1, \ell_o - 1)$ degrees of freedom, that is,

$$F[t] = \frac{\hat{\sigma}_{w_u}^2[t]}{\hat{\sigma}_{w_o}^2[t]} \sim F_{\ell-1, \ell_o-1} \quad (17)$$

This leads to the following sequential F-test (at the α risk level, i.e., false alarm probability equal to α):

$$\begin{aligned}F[t] \leq F_{1-\alpha} &\Rightarrow \text{Accept } H_0 \\ \text{otherwise} &\Rightarrow \text{Accept } H_1\end{aligned}\quad (18)$$

with $F_{1-\alpha} = F_{\ell-1, \ell_o-1}(1 - \alpha)$ indicating the distribution's $(1 - \alpha)$ critical point. An obvious advantage of this approach is that no model reestimation is required in the inspection phase.

Illustrative Example: Nonstationary Random Vibration Modeling and SHM for a Pick-and-Place Mechanism

The Structure and its Nonstationary Random Vibration Response

The system studied in this example is the 2-DOF pick-and-place mechanism mentioned earlier (Fig. 1a). The random vibration response is measured in the same direction as the excitation, using lightweight piezoelectric accelerometers. During a single experiment a single cycle is performed, in which the linear motors move from their rightmost to their leftmost position and back. The measured vibration response is conditioned and driven into a data acquisition

module, which digitizes the signal with a sampling frequency $f_s = 512$ Hz – signal length 10 s ($N = 5,120$ samples). Each signal is subsequently sample mean corrected and normalized (scaled). The frequency range of interest is 5–200 Hz, with the lower limit set in order to avoid instrument dynamics and rigid body modes.

For the SHM problem six damage scenarios are considered, which correspond to the loosening or removal of various bolts at different points of the mechanism (damages A to C and E), loosening the slider of motor B (damage D), and adding a mass at the free end of the slider of motor A (damage F). For each health state, a set of 40 random vibration responses are recorded – see (Spiridonakos and Fassois 2013) for details.

Nonstationary Random Vibration Parametric Modeling (Healthy Structure)

The nonstationary random vibration response (see Fig. 1b) of the healthy structure is now modeled via the stochastic parameter evolution (both SP-TAR and GSC-TAR models) and the deterministic parameter evolution (FS-TAR models) methods using a single data record obtained from the healthy structure. The details for each method are summarized as follows:

Stochastic parameter evolution modeling: SP-TAR models are estimated via the Kalman filter – smoother method (Poulimenos and Fassois 2006) – and GSC-TAR models via the expectation-maximization method (Avendaño-Valencia and Fassois 2013). The innovations variance is in each case estimated via a moving rectangular (600 sample long) window. The following structural parameters are considered: AR order $n_a \in \{3, \dots, 32\}$, with $\{q = 1, \sigma_v^2 = \exp(-11)\}$ and $\{q = 2, \sigma_v^2 = \exp(-24)\}$. The value of σ_v^2 is further optimized by estimating SP/GSC-TAR models with the selected model order and $\sigma_v^2 = \exp(v)$, $v = \{-10, -11, \dots, -30\}$, $q = \{1, 2\}$. The optimal σ_v^2 is determined by considering the RSS and PESS.

Deterministic parameter evolution modeling: Fully parameterized FS-TAR models with trigonometric basis functions of the form

Parametric Nonstationary Random Vibration Modeling with SHM Applications, Fig. 2 Model structure selection for SP-TAR, GSC-TAR, and FS-TAR models: (a) model order selection – RSS/SSS and BIC (the latter normalized between 0 and 1) curves for SP/GSC/FS-TAR models with orders $n \in \{10, \dots, 32\}$. (b) Selection of the subspace dimensionality for FS-TAR models: *top*, BIC of FS-TAR(24) models with $p_a = p_s \in \{3, 5, \dots, 21\}$;

bottom, estimated projection coefficients for each basis dimensionality (continuous lines connect the point estimates and bars indicate $\pm$ one standard deviation). (c) Optimization of σ_v^2 for SP/GSC-TAR models – PESS versus RSS/SSS for SP-TAR(24) and GSC-TAR(24) models. (d) Sample distribution of RSS/SSS and BIC for the selected model structure reestimated for each healthy (H) and damage (A ... F) data record (40 models per health state)

$$\begin{aligned} G_0[t] &= 1, \quad G_{2k-1}[t] \\ &= \sin(2\pi kt/N), \quad G_{2k}[t] \\ &= \cos(2\pi kt/N) \quad k = 1, 2, \dots \end{aligned} \quad (19)$$

are considered. The functional subspace dimensionality p_a corresponds to the number of sine and cosine functions used by the FS-TAR model plus one (the constant component), $t = 1, 2, \dots, N$ is the normalized discrete time, and N the signal length. Parameter estimation is based on ordinary least squares, while the innovations variance is

estimated via the instantaneous method (Poulimenos and Fassois 2006). The following structural parameters are considered: AR order $n_a \in \{3, \dots, 32\}$, $p_a = p_s \in \{3, 5, \dots, 21\}$.

Modeling results: The results of the model structure selection procedure are depicted in Fig. 2a–c). Figure 2a shows the RSS/SSS and normalized BIC for models from each considered class (FS/SP/GSC-TAR), with the selected order ($n_a = 24$) being indicated by an arrow. Figure 2b shows the functional subspace dimensionality

selection for FS models. The top plot shows the BIC of FS-TAR(24) models versus functional basis dimensionality; the selected dimensionality ($p_a = 5$) is indicated by an arrow. The bottom plot shows the absolute value of the estimated coefficients of projection with their corresponding ± 1 standard deviation interval indicated by the bars. It is evident that the standard deviation interval of the estimated coefficients of projection for the basis indices 2 and 4, indicated by the arrows in the plot, consistently contains zero and may be thus removed from the model. An FS-TAR(24)_[3,5] model with functional basis indices $b_a = [0,1,3]$ and $b_s = [0,1,2,3,4]$ is finally selected (i.e., including the functions $G_0[t], G_1[t], G_3[t]$ in the AR subspace and the functions $G_0[t], G_1[t], G_3[t], G_4[t]$ in the innovations variance subspace).

Figure 2c shows the PESS versus RSS/SSS plot for the selection of σ_v^2 for SP-TAR and GSC-TAR models. An arrow indicates the model selected, which corresponds to a “good” compromise between low PESS and RSS/SSS. The selected model structures are SP-TAR(24) with $q = 1$, $\sigma_v^2 = e^{-10}$, and GSC-TAR(24) model with $q = 1$, $\sigma_v^2 = e^{-12}$.

Models of the *selected* (under the healthy condition) structure are subsequently fitted (estimated) for each data record corresponding to the healthy and each damaged state of the structure (40 models per health state, each one based on a distinct data record). In Fig. 2d the sample distribution of RSS/SSS and BIC of the above selected models are presented for the various health states. The FS-TAR model structure uniformly (for all health states and data records) achieves the lowest BIC; although its RSS/SSS values are not minimal.

The “frozen”-type TV-PSDs of the healthy structure, as obtained by the aforementioned three model types and a single data record, are presented in Fig. 3. For purposes of comparison, the nonparametric spectrogram (Gaussian window $\sigma = 8$, $N_{fft} = 1,024$ samples, 51 samples advance ($\sim 5\%$ of N_{fft})) estimate is also shown. While all TV-PSDs are in rough overall agreement, it is obvious that the parametric model-

based ones are much cleaner and informative than their nonparametric (spectrogram) counterpart. This is an important feature of parametric methods.

Nonstationary Vibration Response-Based SHM

As already mentioned the healthy (H) and six damage scenarios (A to F) are considered in SHM, with 40 data records used in each health state.

Two versions of the FS-TAR model parameter-based approach are used: (a) the original version in which the coefficient of projection covariance matrix Σ_o is estimated based on a single data record and (b) an alternative version in which the covariance matrix is estimated based on several (presently 35) data records (using the sample covariance estimator).

Damage detection results using version (a) are depicted in Fig. 4a. All 40 cases corresponding to the healthy structure provide d_M^2 values lying below the selected detection threshold (dashed horizontal line: $\alpha = 10^{-14}$), thus correctly detecting the current healthy state. Also, in all cases corresponding to damages A...D, the obtained d_M^2 values are above the detection threshold, thus correctly detecting damage. Only certain cases corresponding to damages E and F are not properly detected. As indicated by the ROC curves (receiver operating characteristic curves which depict the true positives, TPs, versus false positives, FPs, as the threshold varies) of Fig. 4b, the two versions of the parameter-based approach perform quite adequately and similarly (the performance is almost ideal if damages E and F are excluded).

Next, the FS-TAR residual-based approach is employed using variance estimates obtained via a sliding window of length $\ell = \ell_o = 200$. Figure 4c provides a comparison of the obtained $F[t]$ statistic for a healthy and a damaged (damage D) case. $F[t]$ is, at all times, under the threshold F_u ($\alpha = 10^{-4}$) indicating healthy structure, or above it (for at least some times) indicating damaged structure. As indicated by the ROC curves of Fig. 4d, the residual-based approach

Parametric Nonstationary Random Vibration Modeling with SHM Applications, Fig. 3 Spectrogram and “frozen”-type TV-PSD estimates obtained from estimated

TAR models using a single vibration response of the healthy structure: (a) spectrogram; (b) SP-TAR(24) ($q = 1$); (c) GSC-TAR(24) ($q = 1$); (d) FS-TAR(24)_[3,5]

P

provides, in this application, inferior performance, which is somewhat improved when only two types of damage, namely, C and D, are considered.

Summary

Models and methods for nonstationary random vibration parametric modeling have been presented, with focus on the stochastic parameter evolution (SP-TAR and GSC-TAR models) and deterministic parameter evolution (FS-TAR models) methods. Approaches for nonstationary random vibration-based Structural Health Monitoring (SHM) employing

these models have been also discussed. An illustrative application of the methods to the vibration response modeling and SHM for a laboratory pick-and-place mechanism has been also presented.

Some key points are summarized below:

- Parametric SPE and DPE modelings of nonstationary random vibration are more involved than their nonparametric counterparts but offer unique opportunities for more accurate and compact representations, improved time-frequency resolution, analysis, and SHM. Other areas such as

Parametric Nonstationary Random Vibration Modeling with SHM Applications, Fig. 4 Summary of damage detection results: (a) boxplots of d_M^2 for the parameter-based approach (original version; 40 experiments per health state) – a damage is detected if d_M^2 exceeds the threshold (dashed horizontal line; $\alpha = 10^{-14}$); (b) ROC curves for the original (“th”) and alternative (“smp”) versions of the approach when all damage types are

included (“all”) and when damage types E and F are excluded (“reduced”); (c) performance of the residual-based approach – $F[t]$ versus the threshold ($\ell = \ell_o = 200$, $\alpha = 10^{-4}$) for a single healthy and a damaged state; (d) ROC curves for the residual-based approach when all damage types are included (“all”) and when only damage types C and D are included (“reduced”)

prediction and control may significantly benefit as well.

- SPE modeling is better suited to “slow” or “medium” variations in the nonstationary dynamics, whereas DPE modeling is also suited (with proper functional subspace selection) for “fast” variations.
- The problem of model structure selection is important for both SPE and DPE modelings. Yet, in the latter case, it may be significantly alleviated via the new class of adaptable models (Spiridonakos and Fassois 2014a).
- The problem of local extrema in the (non-convex) estimation criterion is important for both SPE and DPE modeling. Good initial values and careful use of model validation and diagnostic tools are thus necessary (Poulimenos and Fassois 2009b).

- SHM in nonstationary random vibration environments is a rather recent but important area with many potential applications. The presented approaches should be viewed as initial attempts to address the problem.

Passive Control Techniques for Retrofitting of Existing Structures

Alessandro Palmeri

School of Civil and Building Engineering,
Loughborough University, Loughborough,
Leicestershire, UK

Introduction

There are many reasons why existing structures may have insufficient capacity to resist the expected seismic events, or their performance may be considered as unsatisfactory by designers and stakeholders. Examples include (but are not limited to):

- Updated hazard assessment for the site, based on new seismological data and/or improved analyses, that increases the intensity of the design earthquake for the various limit states;
- Change of use of an existing structure that increases the overall risk in case of an earthquake (e.g., an office building which now headquarters strategic departments of civil protection or an industrial building which now contains hazardous substances);
- Design and construction of the structure carried out with obsolete methods (e.g., with insufficient ductility of members and joints).

In such cases, two options are available, namely, building a new structure once the existing one has been knocked down or retrofitting the existing structure, in such a way that enhanced/updated performance criteria are satisfied. In many cases, the second option is more advantageous, reducing direct and indirect costs.

Traditional retrofitting of building structures can be achieved by locally increasing stiffness and strength of structural members (e.g., Wu et al. 2006; Hueste and Bai 2007; Ozcan et al. 2008). This can affect both the demand (as the modal frequencies would increase and may have either a beneficial or a detrimental effect) and the capacity (as the overall resistance will be higher). However, traditional retrofitting (e.g., adding steel or FRP jackets and plates to increase the axial and bending performance of RC columns and beams) may be very expensive due to the large number of local interventions and may also prevent the use of the structure for many months (with the associate indirect costs for the loss of use).

A different retrofitting approach consists of equipping the existing structure with passive control devices, i.e., dampers and isolators (e.g., Soong and Spencer 2002; Dargush and Sant 2005; Di Sarno and Elnashai 2005). Such devices are said to be “passive” because they do not require any power supply to work (unlike “active” and “semi-active” devices). Dampers,

commonly placed in the superstructure of buildings, allow reducing the seismic demand by increasing the overall energy dissipation capability, although they may also increase the stiffness of the structure. Viscous, viscoelastic and elastoplastic mechanisms of energy dissipation are typically exploited in this type of devices. Conversely, isolators placed between the superstructure and the foundation of a building improve the seismic performance by increasing the fundamental period of vibration of the overall structural system, in such a way that most of the energy of the earthquake is filtered as the seismic motion of the superstructure is decoupled (i.e., isolated) from the ground. High-damping rubber bearings (HDBRs) and friction pendulum bearings (FPBs) are among the most popular types of isolators.

In the following, the effectiveness of different passive control techniques for earthquake protection will be demonstrated by considering the seismic response of SDoF (single-degree-of-freedom) oscillators, with and without dampers, namely:

- Fluid viscous dampers (FVD);
- Elastomeric viscoelastic dampers (EVDs);
- Steel hysteretic dampers (SHDs).

Other control techniques can be adopted in the professional practice, which exploit different dynamic phenomena. This is the case of tuned mass dampers (TMDs), including sloshing liquid dampers (SLDs), in which a secondary mass is tuned to the mode of vibration of the existing structure, allowing part of the seismic energy to be transferred to the TMD, where this energy can be dissipated (e.g., Hoang et al. 2008; Lin et al. 2011). Another possibility is to exploit rocking mechanisms, in which part of the seismic energy is transformed into potential energy, as the center of mass of the structure raises when the structure uplifts, and then this energy is dissipated through impacts (e.g., Marriott et al. 2008; Palmeri and Makris 2008). These alternative control techniques are not discussed in the following, as they are not as effective as dampers and isolators in the seismic protection of

building structures (e.g., TMDs are very effective against wild loads, while rocking is particular effective for bridge structures).

Similarly, seismic isolators are not treated in the following, as this technique is more appealing and economically advantageous for new structures rather than for the seismic retrofitting of existing structures. It must be said, however, that in some situations the installation of dampers within an existing building can be very difficult, e.g., because of the large forces that such devices need to transfer to the old structural members, and in this case base isolation system may become the only viable solution.

Governing Equations

The dynamic equilibrium at a generic time t for a SDoF oscillator subjected to seismic input can be written as:

$$m\ddot{u}(t) + f_S(t) + f_D(t) = -m\ddot{u}_g(t), \quad (1)$$

where m is the mass of the oscillator; $u(t)$ is the time history of the relative displacement of the mass with respect to the ground; $\ddot{u}_g(t)$ is the absolute acceleration of the ground; $f_S(t)$ and $f_D(t)$ are the time-varying reaction forces due to stiffness and damping mechanisms. In the above expression, the first term $m\ddot{u}(t) = f_I(t)$ can be interpreted by a ground observer as the inertial force experienced by the mass, while $-m\ddot{u}_g(t) = F(t)$ is the dynamic force induced by the ground shaking. The total inertial force, within a Galilean reference frame, is proportional to the absolute acceleration of the mass m , that is: $f_I^{(G)}(t) = m(\ddot{u}(t) + \ddot{u}_g(t)) = f_I(t) - F(t)$. For a linear system, $f_S(t) = k u(t)$ and $f_D(t) = c\dot{u}(t)$ are proportional to the relative displacement and velocity of the mass through the elastic stiffness k and the viscous damping coefficient c .

Multiplying both sides of Eq. 1 by the infinitesimal relative displacement $du(t)$, and integrating from 0 to the generic time instant t , one obtains:

$$\begin{aligned} \int_0^t m\ddot{u}(\tau)du(\tau) + \int_0^t f_S(\tau)du(\tau) \\ + \int_0^t f_D(\tau)du(\tau) = \int_0^t F(\tau)du(\tau), \end{aligned} \quad (2)$$

which gives the energy balance of the dynamic system over the time interval $[0, t]$ (Uang and Bertero 1990).

Assuming that the oscillator is initially at rest (i.e., $u(0) = 0$ and $\dot{u}(0) = 0$), it can be easily shown that the first integral in the left-hand side is the kinetic energy of the system at the generic time t :

$$T(t) = \frac{1}{2}m\dot{u}(t)^2 = \int_0^t m\ddot{u}(\tau)du(\tau), \quad (3)$$

while the integral in the right-hand side gives the cumulative work done by the seismic input:

$$W_{in}(t) = \int_0^t F(\tau)du(\tau). \quad (4)$$

Additionally, the integral of the linear-elastic stiffness term gives the potential energy of the oscillator:

$$V(t) = \frac{1}{2}ku(t)^2 = \int_0^t ku(\tau)du(\tau), \quad (5)$$

and the linear-viscous damping term provides the energy dissipation:

$$W_D(t) = \int_0^t f_D(\tau)du(\tau) = c \int_0^t \dot{u}(\tau)^2 d\tau. \quad (6)$$

Taking into account Eqs. 3, 4, 5, and 6, it follows that for a linear SDoF oscillator the energy balance at a generic time t can be expressed as (Uang and Bertero 1990):

$$E(t) = T(t) + V(t) = W_{in}(t) - W_D(t), \quad (7)$$

where $E(t)$ is the total mechanical energy stored within the system at time t . Since the potential for damaging the structure increases with this quantity, passive control techniques aim to reduce $E(t)$ either by reducing the input energy $W_{in}(t)$ (e.g.,

Passive Control Techniques for Retrofitting of Existing Structures, Fig. 1 Seismic input. Time history of ground acceleration (a) and response spectrum in terms of pseudo-acceleration (b)

changing the stiffness) or increasing the energy dissipation capacities of the structure (e.g., using dampers to increase $W_D(t)$).

For illustration purposes, specific examples will be provided in the next three sections for different types of dampers. The method used for comparing the different systems will be briefly discussed in the next subsection.

Seismic Excitation and Performance Analysis

The seismic performance of any control technique is greatly influenced by the characteristics of the ground motion, e.g., the peak ground acceleration (PGA), the duration of the event, the variation with time of both amplitude and frequency content, as well as by the characteristics of the existing structure, e.g., modal frequencies, available ductility, overstrength, etc. In order to make a fully comprehensive comparison between different techniques, all these aspects should be considered and the results carefully analyzed. This is far beyond the scope and the limits of the present contribution, and for this reason, a very simple signal has been used throughout as seismic input for our numerical investigations, namely, a harmonic function in which both amplitude and frequency vary with time, i.e., an amplitude-modulated cosine-sweep function. The mathematical expression of the envelope of the signal is given by

$$e_g(t) = \begin{cases} a_g \sin\left(\frac{\pi t}{t_g}\right), & \text{if } 0 \leq t \leq t_g; \\ 0, & \text{otherwise;} \end{cases} \quad (8)$$

and the ground acceleration is

$$\ddot{u}_g(t) = e_g(t) \cos\left(\frac{\omega_g^2 t^2}{2N_g\pi}\right), \quad (9)$$

where a_g is the PGA and $t_g = 2N_g\pi/\omega_g$ is the duration of the signal, which in turn depends on the mean circular frequency ω_g and number of cycles N_g of the ground motion. As an example, for $\omega_g = 12.5$ rad/s and $N_g = 8.25$, the duration of the signal is $t_g = 4.15$ s. The accelerogram obtained with this set of parameters is shown within Fig. 1a, in which the red half sine gives the envelope.

This signal has then been used in the following to investigate the effects of different protection systems, and Fig. 1b shows the corresponding elastic response spectrum in terms of pseudo-acceleration, $S_{pa}(T_i)$, which is mathematically defined as:

$$S_{pa}(T_i) = \left(\frac{2\pi}{T_i}\right)^2 \max_{0 \leq t \leq t_g} \{|u(t)|\}, \quad (10)$$

and represents a measure of the maximum force experienced by the SDoF oscillator of natural period T_i during the seismic event. The three vertical dashed lines denote the three natural periods $T_i = 0.3, 0.5$, and 0.8 s considered in the analysis, which corresponds to frequency ratios $\beta_i = \omega_g/\omega_i$ equal to $0.60, 0.99$, and 1.59 , i.e., “stiff,” “resonant,” and “flexible” test structures.

Passive Control Techniques for Retrofitting of Existing Structures, Fig. 2 Floor spectra. Stiff (dashed line), Resonant (solid line) and Flexible (dotted line) existing (primary) structure

The value assumed for the equivalent viscous damping ratio is $\zeta_0 = c/c_{\text{crit}} = 0.02$, being $c_{\text{crit}} = 2\sqrt{km}$ the viscous damping coefficient for a critically damped system. Even though quite small, this value of ζ_0 is reasonable for an undamaged structure within the linear-elastic range.

The semilogarithmic graph of Fig. 2 compares the so-called floor spectra for the three SDoF oscillators with the selected natural periods T_i . Each floor spectrum is obtained by using the absolute acceleration of the i th (primary) oscillator, $\ddot{u}^{(\text{abs})}(t) = \ddot{u}(t) + \ddot{u}_g(t)$, as seismic input for a (secondary) oscillator with natural period T_j and viscous damping ratio ζ_0 . The floor spectrum $S_f(T_i, T_j)$ then gives the maximum pseudo-acceleration for a light attachment (of natural period $T_j = 2\pi/\omega_j$) to the primary oscillator (of natural period $T_i = 2\pi/\omega_i$). The governing equations are:

$$\begin{cases} \ddot{u}(t) + 2\zeta_0 \omega_i \dot{u}(t) + \omega_i^2 u(t) = -\ddot{u}_g(t); \\ \ddot{y}(t) + 2\zeta_0 \omega_j \dot{y}(t) + \omega_j^2 y(t) = -(\ddot{u}(t) + \ddot{u}_g(t)), \end{cases} \quad (11)$$

where $y(t)$ is the relative displacement of the secondary mass with respect to the primary one, and the assumption is made that the secondary mass is light enough for its feedback force on the primary mass to be negligible. The reason why the floor spectra are considered as part of this

study is because they allow quantifying the maximum force that a seismic event induces in secondary substructures attached to the primary structural system and then can give an indication about the effectiveness of different retrofitting strategies in terms of building content, including building services (e.g., Sackman and Kelly 1979; Muscolino and Palmeri 2007). As expected, (i) each floor spectrum of Fig. 2 takes the maximum value for $T_j = T_i$, i.e., when primary and secondary oscillators are tuned, and (ii) the maximum amplification is observed for $T_i = 0.5$ s (solid line), i.e., for the resonant primary oscillator.

Fluid Viscous Dampers (FVDs)

Viscous fluids have the potential to dissipate large amount of energy, as friction forces arise when they are forced to flow through orifices (e.g., Lee and Taylor 2001; Martinez-Rodrigo and Romero 2003; Molina et al. 2004; Marano et al. 2013). Typically, a fluid viscous damper (FVD) consists of a stainless steel piston traveling through two adjacent chambers filled with silicone oil (often chosen because it is fire resistant, nontoxic, and stable for long periods of time). The movement of the piston causes the silicone oil to flow through an orifice in the piston head, transforming part of the mechanical energy into heat, which is then dissipated into the atmosphere.

force under harmonic cycles for different values of the velocity exponent: $\alpha = 1.00$, solid thick line; $\alpha = 0.90$, dotted line; $\alpha = 0.30$, dashed line; $\alpha = 0.10$, solid thin line

Figure 3 shows two recent applications of FVDs for the seismic retrofitting of existing structures in Italy, namely, a prefabricated industrial building in Imola (Fig. 3a), necessary after the 2012 Northern Italy earthquakes, and building “A” of the Faculty of Engineering of the University of L'Aquila (Fig. 3b), required after the 2009 L'Aquila earthquake. In both cases, the presence of the control devices increases the damping capacity of the structure and improves their seismic behavior.

The reaction force $f_{\text{FVD}}(t)$ exerted by FVDs depends on the relative velocity $\dot{u}(t)$ between the opposite ends of the device, and their nonlinear force–velocity relationship is generally expressed as (e.g., Lin and Chopra 2002)

$$f_{\text{FVD}}(t) = c|\dot{u}(t)|^\alpha \text{sgn}[\dot{u}(t)], \quad (12)$$

where c is the damping coefficient (measured in $\text{kN s}^\alpha/\text{m}^\alpha$); α is a velocity exponent, which usually takes a value between 0.3 and 0.9; $|\cdot|$ stands for the absolute value; and $\text{sgn}[\cdot]$ is the signum function, which gives -1 if the argument within square brackets is negative, $+1$ if positive, and 0 if the argument is zero.

Figure 4 illustrates the effect of the velocity exponent α in terms of hysteresis loop $f_{\text{FVD}}(t) - u(t)$ (Fig. 4b) and time history of the reaction force $f_{\text{FVD}}(t)$ (Fig. 4a). Assuming a harmonic displacement $u(t) = u_{\text{max}} \sin(2\pi t/T)$ with period $T = 0.5$ s, it is shown that reducing the exponent α changes the hysteresis loop, from the ellipse

typical of the linear behavior ($\alpha = 1$, thick solid line) to a rectangle ($\alpha \rightarrow 0$). In both graphs, the maximum force $f_{D,\max} = 2\pi c u_{\max}/T$ experienced by the linear device ($\alpha = 1$) is used to make dimensionless the vertical axis. This reveals that, if the damping coefficient c and the period of oscillation T are kept constant, the peak force in the FVD decreases with α ; on the other hand, the less α , the larger the reaction force for small velocities.

More precisely, one can prove that linear ($\alpha = 1$) and nonlinear ($0 < \alpha < 1$) devices experience the same reaction force if the velocity takes the value:

$$|\dot{u}(t)| = v_D = \left(\frac{c_{\text{nonlin}}}{c_{\text{lin}}} \right)^{\frac{1}{1-\alpha}}; \quad (13)$$

for $|\dot{u}(t)| > v_D$ the linear device reacts with higher forces, and the opposite happens for $|\dot{u}(t)| < v_D$. Given that the maximum velocity tends to increase with the amplitude of the oscillatory motion, it follows that nonlinear VFDs, with a small velocity exponent (say $\alpha < 0.50$), are more efficient in the seismic retrofit of existing structures, as comparatively they require lesser deformations to apply the control forces.

When the nonlinear FVD is added to the SDoF oscillator, the equation of seismic motion becomes:

$$\ddot{u}(t) + 2\zeta_0 \omega_i \dot{u}(t) + \omega_i^2 u(t) + \frac{1}{m} f_{\text{FVD}}(t) = -\ddot{u}_g(t), \quad (14)$$

and any reliable scheme of numerical integration (e.g., the Newmark- β method) can be used to evaluate the dynamic response.

In order to allow assessing the performance of FVDs in improving the seismic behavior of an existing structure, Fig. 5 compares the seismic response of three pairs of SDoF oscillators, with and without the additional FVD, for the three periods of vibration T_i selected in the previous section, namely, $T_i = 0.3$ s (stiff oscillator) for the top row, $T_i = 0.5$ s (resonant oscillator) for the central row, and $T_i = 0.8$ s (flexible oscillator) for the bottom row.

The accelerogram $\ddot{u}_g(t)$ is the sweep function of Eq. 9 (see Fig. 1a), and the PGA is $a_g = 0.25$ g, which is representative of a moderate seismic event. The viscous damping ratio of the existing structure is assumed to be $\zeta_0 = 0.02$, while the additional FVD is characterized by the mechanical parameters $c/m = 1.59 \text{ m}^{0.7} \text{ s}^{-1.7}$ and $\alpha = 0.3$.

The time histories of the mass displacement, $u(t)$, are plotted in the three graphs in the first column (Fig. 5a–c), using lighter dashed lines for the seismic responses without control devices and thick solid lines when the nonlinear FVD is added. In all the three cases, a similar reduction in the maximum displacements is observed.

The second column from the left (Fig. 5d–f) presents the comparison in terms of force–displacement hysteresis loops: namely, the narrow pseudo-ellipses show the energy dissipated through the inherent viscous damping of the SDoF oscillator, while the pseudo-rectangles are the hysteresis loops associated with the additional nonlinear FVD. In all the cases, the latter source of energy dissipation is larger, which explains why the seismic displacements are reduced. This is confirmed by the graphs in the third column (Fig. 5g–i), in which the comparison is presented in terms of time histories of various forms of energy and the external work. The two dashed lines are used for the oscillator without FVD, and specifically to plot the cumulative work done by the seismic input, $W_{\text{in}}(t)$, and the total mechanical energy $E(t)$. Solid lines are used for the oscillator with the FVD: in this case, the $W_{\text{in}}(t)$ is the highest among the solid curves, while the total mechanical energy is the envelope of potential energy $V(t)$ and kinetic energy $T(t)$. The other two solid lines are used to plot the energy dissipated by the two damping mechanics, i.e., the additional FVD (black, high curve) and the inherent damping of the existing structure (gray, low curve).

Additionally, the floor spectra $S_f(T_j)$ depicted in the fourth column (Fig. 5j–l) demonstrate that the additional FVD allows reducing the maximum accelerations experienced by any attachment to the building structure (as in previous cases, solid and dashed lines are used for the seismic response with and without additional

control device). This is particularly significant if primary and secondary structure are tuned (i.e., $T_i = T_j$).
